MEASUREMENT OF FEMORAL NECK ANTEVERSION AND INCLINATION

A radiographic study in children

by Lars Henriksson, Department of Paediatric Radiology, University of Goteborg, Goteborg, Sweden.

ABSTRACT. A general computer based method for determination of anatomical angles from roentgenograms was developed This method is especially designed for determination of anteversion and inclination of the femoral neck The x-ray exposures are performed with the child in a constant supine position and the lower leg hanging freely. Three films are exposed for each leg – a frontal and a lateral view of the hip and a third lateral view of the knee By the three films the orientation of the femur is defined relative to a coordinate-system. From coordinates on the films of the axes and points of the femur the angles are calculated by mini-computer. The computer program (ANTEV in FORTRAN) is based on the general principles for central projection The present computerized method does not presuppose an exactly defined position of the patient The accuracy of measurement is $\pm 2^\circ$ (SD) for inclination and $\pm 3^\circ$ (SD) for anteversion The angles have been defined relative to the long ideal axis of the femoral shaft

All measurements of anteversion presuppose a plane of reference – the anteversion is defined as the angle between the femoral neck and the plane of reference Two planes of reference were studied, the frontal plane and the tangential plane to the dorsal parts of the femoral condyles measured by fluoroscopy

The anteversion and inclination in normal children between the age of 3 and 16 years were determined with special reference to magnitude and biological variation In normal children the anatomical anteversion, i.e the angle between the femoral neck and the tangential plane to the femoral condyles, diminishes slightly in girls, but not in boys, during childhood However, in both sexes there is an evident decrease of the functional anteversion, i.e the angle between the femoral neck and the frontal plane This decrease has been found to be a result of a change in the neutral position of the femur, which changes from a relative outward rotation to a relative inward rotation during childhood Both the anatomical and functional anteversion have a wide biological variation $15^\circ - 20^\circ$ (2SD) During childhood inclination decreases slightly in both sexes.

A consecutive follow up study in children with CDH, treated with a von Rosen splint in the neonatal period, was performed As a group the children in this series appear to have normal angles of anteversion and inclination at the age of 6 – 9 years

[illegible]

supine with the lower leg hanging freely, the inclination of the tangential plane to the [illegible] termined by fluoroscopy. If the inclinations are mainly symmetric, a torsion is unlikely to be present in the fracture On the other hand, if there is an evident asymmetry between the two sides, a torsion exceeding 10° is probable.

The accuracy of measurement of conventional biplanar radiographic methods for determination of anteversion was studied theoretically. By applying the Gaussian law for propagation of errors to the trigonometric formula for the Rippstein method, the accuracy of measurement was estimated The accuracy of measurement was found to be $\pm 5^\circ$ (SD), compared with $\pm 3^\circ$ (SD) for the computerized method, when determining anteversion of the femoral neck.

Key words Accuracy of measurement, radiography, angle, radiography, anteversion, femur, femoral neck, functional anteversion, hip dislocation, congenital, inclination, torsion, fractures

INTRODUCTION

Many radiological methods for determining anatomical angles in particular the anteversion angle of the femoral neck have been published since Drehmann (1909) who determined anteversion by fluoroscopy

Measurement of femoral neck anteversion is usually performed according to the biplanar method described by Ryder & Crane (1953) and Rippstein (1955) Cyvin (1977) used the Rippstein method in a follow up study of children with hip instability at birth and this method was also used recently by Benum et al (1979) who measured femoral torsion after fractures

The possibility of correct determination of angles is reduced by the many sources of error in the measurement procedure Errors of measurement on the x ray films and incorrect positioning of the object are factors of fundamental importance A third source of error is incorrect adjustment of the x ray apparatus Estimation of the magnitude of these errors is necessary in order to be able to assess how accurately angles can be determined from x ray films

Earlier authors have estimated the errors and their sources in the biplanar methods (Ryder & Crane 1953 Dunlap et al 1953 Rippstein 1955 Gross & Haike 1970 Elsasser & Walker 1973) but the accuracy of measurement expressed as the standard error (SD) has not been fully established for clinical use in these studies The biplanar determination of anteversion is frequently performed by trigonometric calculations from films by means of tables, formulas or nomograms (Leger 1952 Dunlap et al 1953 Ryder & Crane 1953 Billing 1954 Rippstein 1955, Edholm 1972)

A simple biplanar method based on descriptive geometry for determination of the anteversion has been elaborated by Norman (1965) This method also renders determination of the inclination and fracture angles possible

A general solution to the problem of determination of angles from x ray films taken in two directions has been presented by Edholm (1966) This author provides a comprehensive analysis of the possibilities of the nomographic method On the basis of his results an instrument meeting the needs for accurate measurement in routine radiological work was constructed

Developments in the field of computer technique during recent years with increased access to computers make it natural to replace the nomographic methods by computer processing Computer evaluation of the results of measurements makes it possible to calculate the above mentioned errors of measurements without additional manual work as well as to determine additional angles from the data given

The aim of this study was

1 To elaborate a method for the determination of anatomical angles from roentgenograms using a computer technique

2 To establish the accuracy of this method with special reference to the anteversion and inclination of the femoral neck

3 To study the variation of anteversion and inclination in normal children

4 To perform a follow up study of children with congenital dislocation of the hip (CDH) treated with a von Rosen splint in the neonatal period

5 To study torsion in healed femoral shaft fractures in children

Chapter I

COMPUTERIZED DETERMINATION OF ANGLES

In collaboration with Tomas Blomberg

From the Department of Paediatric Radiology, University of Göteborg, Göteborg, Sweden

The analysis presented here represents a new general principle, using computer technique, for the determination of different anatomical angles from x ray films Therefore it was found necessary – first to make a theoretical analysis of the general principles for determination of angles from x ray projections, and then to apply this method and evaluate its reliability by computer technique using a model and an anatomical preparation

Theoretical considerations

The image obtained on an x ray film is a central projection of the object in one plane (the film) with its centre at the focus (the radiation source) Straight lines in the object are projected as straight lines on the film If a line l in the object is reproduced in a projection with its centre F_1 *on plane Π_1 in the line l the line l will be positioned in the plane that passes through the point* F_1 and the line l' (fig 1) This plane may be denoted $\Pi(F_1, l)$

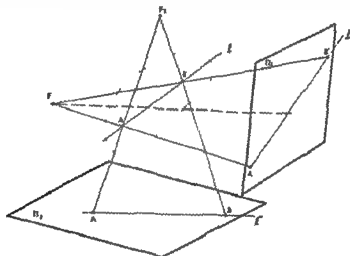

Fig 1

If the projections l' and l'' of the line l in two different planes Π_1 and Π_2, using the centres F_1 and F_2 respectively are known the line l can be calculated as the intersection between the planes $\Pi(F_1, l')$ and $\Pi(F_2, l'')$ Thus a line is defined if its projections in two different planes are known

An angle between two lines in a reproduced object can be calculated if the projections of the two lines in two different planes are known. The directions of the two lines in space are determined and from them the angle can then easily be calculated (the scalar product of the normed directional vectors for the two lines gives the cosine of the angle) Calculations of this type are laborious to perform manually but can easily be performed on a computer The computer must be fed with coordinates for suitable points on the various films and some angles and distances determining the position in space for the films and foci concerned

The above mentioned asymmetric estimation of the point A suggests another way of determining a point. Let us assume that we have two projections (films) of an object and that the point sought can be seen in the first film but not in the second. In the second film, however, a line on which the point is known to lie can be seen. In this case, the point A must be determined from a point A' in a plane (film) Π_1 and a line 1'' in another plane Π_2 (fig. 3). A is determined in this case as the point of intersection between the line $A'F_1$ and the plane $\Pi(F_2, 1'')$ through F_2 and the line 1'' on which point A is known to lie. This method of identifying the point may be said to be indirect, in contrast to the former direct way with points on the two films.

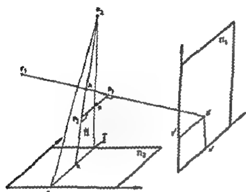

Fig. 2

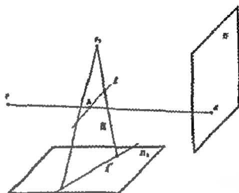

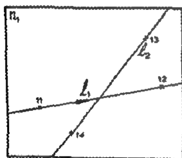

Fig. 3

Let us now revert to the problem of determining angles. Two examples of methods for determining angles from two projections will be given. These definitions have been used in practical tests with steel triangles (page 14). Several examples of definitions of angles of the femur will be given in the following.

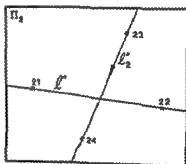

Fig. 4

The first example corresponds to direct determination of an angle, denoted V_1, both sides being assumed to be visible in both projections (fig. 4). The projection l_1' of the first side l_1 in plane Π_1 passes through points 11 and 12 and corresponds to the positive direction of the line. The projection of l_1 in plane Π_2 passes through the points 21 and 22. These points can be suitably chosen after marking the line l_1' and need not correspond to the points 11 and 12. Similarly, the side l_2 is assumed to be given by the points 13, 14, 23 and 24, the positive direction of l_2 corresponding to the direction from 23 to 24.

An alternative method for determining the line 1 from the projections in plane Π_1 and Π_2 is as follows Let us assume that A" and B" are projections in plane Π_2 of two given points A and B on 1 (fig 1) Starting from points A" and B" and the projection 1' above, the line 1 can be de termined We begin by determining the plane $\Pi(F_1, 1')$, which passes through line 1 and point F_1, and then determine point A as the central projection of point A" in plane $\Pi(F_1, 1')$ using F_2 as the centre Thus A is determined as the point of intersection between plane $\Pi(F_1, 1)$ and the line passing through points A" and F_2 In analogy with this, the point B can be determined and the line 1 will be the line joining A and B

An advantage of the latter method of determining line 1 is that the points A" and B" can be made to contain information on the positive direction of the line if this is defined A and B may, for example, be chosen so that the positive direction of the line corresponds to the direction from A to B This is of importance when determining angles between lines since it may otherwise be difficult to distinguish between an angle and its supplementary angle

The latter method of determining the line 1 can be generalized by using the projection B‴ of point B in a third plane Π_3 and a third centre F_3 instead of B" (This way of determining a line will be used for the diaphyseal axis below)

The above considerations form the foundation for determination of angles that can be seen direct ly on the films, i e the sides of the angle can be identified directly on the films Such an example is the inclination of the femoral neck (see below) It is also of interest, however, to study angles determined indirectly from quantities (lines, points and planes) other than two angle sides Cer tain lines, points or planes in the object can be identified on the x ray films, and the angle can then be calculated from these An example is the determination of anteversion angles (see below)

The determination of planes and points from projections will now be discussed and we will re vert to indirect determinations of lines and angles later

The only case in which a plane can be seen in a projection is when the plane passes through the *centre of the projection (the focus) and can be represented in the projection plane (the film) by* a line

A point A in an object can be defined in several ways The most direct method is to define its central projections A' and A" in two planes Π_1 and Π_2 with respect to the centres F_1 and F_2 (fig 2) The point A can in this case be determined as the point of intersection between the line through A' and F_1, which may be denoted by $A'F_1$, and the line between A" and F_2 denoted by $A''F_2$ This raises a special problem in practice Let us assume that the points A' and A" have been defined by determining coordinates (x', y') and (x", y") in planes Π_1 and Π_2 Owing to er rors of measurement, the two lines $A'F_1$ and $A''F_2$ will generally not intersect The natural pro cedure in this case is to estimate A as the midpoint *P of the section P_1P_2, with the points P_1 and* P_2 on the lines $A'F_1$ and $A''F_2$ which is at right angles to these lines (fig 2) We call this point P the crossing point of the lines $A'F_1$ and $A''F_2$

In this case the sought point is overdetermined Three coordinates suffice to define the point *From, for example, x', y' and x"*, A can be determined as the intersection between the line $A'F_1$ and the plane $\widetilde{\Pi}$ that passes through F_2 and the line $\widetilde{1}$ in the plane Π_2 with the equation x = x" in the corresponding coordinate system This is an asymmetric method of determining the point A and does not utilize the information carried by the coordinate y' The estimate P as the cross ing point defined above, on the other hand, is a symmetric estimate and may be regarded as a sort of least square fit The distance $d = PP_1 = PP_2$ *(fig 2) may be used as an indication of the* degree of accuracy with which point A can be determined

The above mentioned asymmetric estimation of the point A suggests another way of determining a point Let us assume that we have two projections (films) of an object and th … ght can be seen in the first film but not in the se … the point … A … is determined in this case as th … the line A'F$_1$ and the plane $\overline{\Pi}$(F$_2$ l'') through F$_2$ and the line l'' on which point A is known to be This … it may be said to be indirect …

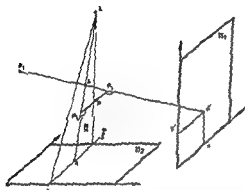

Fig 2

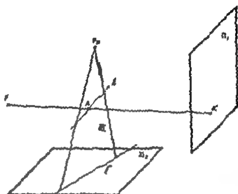

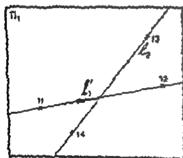

Fig 3.

Let us now revert to the problem of determining angles Two examples of methods for determining angles from two projections will be given These definitions have been used in practical tests with steel triangles (page14) Several examples of definitions of angles of the femur will be given in the following

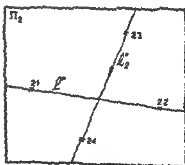

Fig. 4

The first example corresponds to direct determination of an angle … les being assumed to be visible in both projections (fig 4) … Π_1 passes through points 11 … in plane … projection of l_1 in p … These points can be suitably chosen after marking … do not correspond to the points 11 and 12 Similarly, the side l_2 is assumed to be given by the points 13, 14, 23 and 24, the positive direction of l_2 corresponding to the direction from 23 to 24

An alternative method for determining the line l from the projections in plane Π_1 and Π_2 is as follows Let us assume that A" and B" are projections in plane Π_2 of two given points A and B on l (fig 1) Starting from points A" and B" and the projection l' above, the line l can be de termined We begin by determining the plane $\Pi(F_1, l')$, which passes through line l and point F_1, and then determine point A as the central projection of point A" in plane $\Pi(F_1, l')$ using F_2 as the centre Thus A is determined as the point of intersection between plane $\Pi(F_1, l)$ and the line passing through points A" and F_2 In analogy with this, the point B can be determined and the line l will be the line joining A and B

An advantage of the latter method of determining line l is that the points A" and B' can be made to contain information on the positive direction of the line if this is defined A and B may, for example, be chosen so that the positive direction of the line corresponds to the direction from A to B This is of importance when determining angles between lines since it may otherwise be difficult to distinguish between an angle and its supplementary angle

The latter method of determining the line l can be generalized by using the projection B‴ of point B in a third plane Π_3 and a third centre F_3 instead of B" (This way of determining a line will be used for the diaphyseal axis below)

The above considerations form the foundation for determination of angles that can be seen direct ly on the films, i e the sides of the angle can be identified directly on the films Such an example is the inclination of the femoral neck (see below) It is also of interest, however, to study angles determined indirectly from quantities (lines, points and planes) other than two angle sides Cer tain lines, points or planes in the object can be identified on the x ray films and the angle can then be calculated from these An example is the determination of anteversion angles (see below)

The determination of planes and points from projections will now be discussed and we will re vert to indirect determinations of lines and angles later

The only case in which a plane can be seen in a projection is when the plane passes through the centre of the projection (the focus) and can be represented in the projection plane (the film) by a line

A point A in an object can be defined in several ways The most direct method is to define its central projections A' and A" in two planes Π_1 and Π_2 with respect to the centres F_1 and F_2 (fig 2) The point A can in this case be determined as the point of intersection between the line through A' and F_1, which may be denoted by $A'F_1$, and the line between A" and F_2, denoted by $A''F_2$ This raises a special problem in practice Let us assume that the points A' and A have been defined by determining coordinates (x', y') and (x", y ') in planes Π_1 and Π_2 Owing to er rors of measurement, the two lines $A'F_1$ and $A''F_2$ will generally not intersect The natural pro cedure in this case is to estimate A as the midpoint P of the section P_1P_2 with the points P_1 and P_2 on the lines $A'F_1$ and $A''F_2$ which is at right angles to these lines (fig 2) We call this point P the crossing point of the lines $A'F_1$ and $A''F_2$

In this case the sought point is overdetermined Three coordinates suffice to define the point From, for example, x', y' and x", A can be determined as the intersection between the line $A'F_1$ and the plane $\tilde{\Pi}$ that passes through F_2 and the line $\tilde{l}$ in the plane Π_2 with the equation x = x in the corresponding coordinate system This is an asymmetric method of determining the point A and does not utilize the information carried by the coordinate y' The estimate P as the cross ing point defined above, on the other hand, is a symmetric estimate and may be regarded as a sort of least square fit The distance $d = PP_1 = PP_2$ (fig 2) may be used as an indication of the degree of accuracy with which point A can be determined

The above mentioned asymmetric estimation of the point A suggests another way of determining a point Let us assume that we have two projections (films) of an object and that the point sought can be seen in the first film but not in the second In the second film, however, a line on which the point is known to lie can be seen In this case the point A must be determined from a point A' in a plane (film) Π_1 and a line l' in another plane Π_2 (fig 3) A is determined in this case as the point of intersection between the line A F_1 and the plane $\overline{\Pi}(F_2, l)$ through F_2 and the line l on which point A is known to lie This method of identifying the point may be said to be in direct in contrast to the former direct way with points on the two films

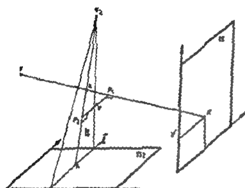

Fig 2

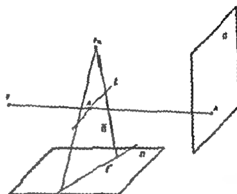

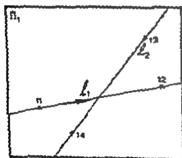

Fig 3

Let us now revert to the problem of determining angles. Two examples of methods for determining angles from two projections will be given These definitions have been used in practical tests with steel triangles (page 14) Several examples of definitions of angles of the femur will be given in the following

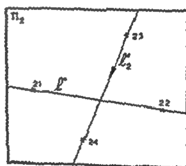

Fig. 4

The first example corresponds to direct determination of an angle denoted V_1, both sides being assumed to be visible in both projections (fig. 4) The projection l_1 of the first side l_1 in plane Π_1 passes through points 11 and 12 and corresponds to the positive direction of the line The projection of l_1 in plane Π_2 passes through the points 21 and 22 These points can be suitably chosen after marking the line l_1 and need not correspond to the points 11 and 12 Similarly, the side l_2 is assumed to be given by the points 13 14 23 and 24 the positive direction of l_2 corresponding to the direction from 23 to 24

In the second example which is an indirect determination of an angle, we assume that the side is visible in both films and that its positive direction can be identified in film 2 We assume that the side l_2 is visible in film 1 but not in film 2, but that the projection P " of a point P that is known to lie on the side l_2 is visible (fig 5) The positive direction of the line l_2 is assumed t correspond to the direction from the point of intersection of these lines (apex of the angle) to the point P With this information, an angle, denoted V_2, is uniquely defined

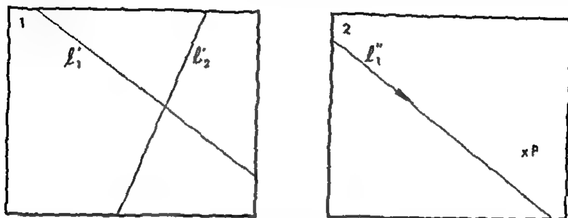

Fig 5

The angle V_2 can be determined as follows The point P can be determined as the point of intersection between the line P 'F_2 and the plane $\Pi(F_1, l_2')$ This is equivalent to the above described indirect determination of a point The side l_1 is directly equivalent to definition of a line as discussed above, and the apex of the angle can be determined as the point of intersection Q betwee l_1 and the plane $\Pi(F_1, l_2')$ The other side, l_2 of the angle V_2 sought will then be given by the line Q P (fig 6)

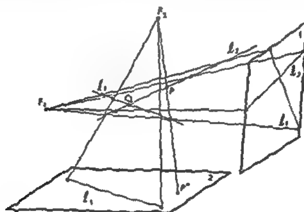

Fig 6

Definitions for determination of angles of the femoral neck

The determination of two femoral angles, the anteversion and the inclination will be discussed

The method we have studied is based on examining the patient in the supine position with the femur horizontal and the lower leg hanging freely Three x ray projections are taken the frontal projection at the hip with vertical beam direction, the lateral projection at the hip and the lateral projection at the knee, both with horizontal beam direction Figures 7 – 9 show these three projections for a bone preparation positioned so as to correspond to the patient position described above For definitions of angles the long femoral axis was used The short proximal femoral axis can also be used but angles relating to this axis are not discussed in this paper

In frontal projection the femoral-diaphyseal axis is readily identified as the midline of the diaphysis, marked by the two points 11 and 12. In the lateral projection, however, the diaphysis is curved. Two films are therefore used to determine the so called ideal shaft axis (Billing 1954). A point 21 is indicated in film 2 (fig. 8) as the hypothetical point of intersection of the proximal extension of the midline of the diaphysis with the femoral neck and a point 31 in the midline of the condylar mass on the distal extension of the midline of the diaphysis (fig. 9). The femoral diaphyseal axis is thereby determined. The positive direction of the axis is defined as the direction from the hip to the knee.

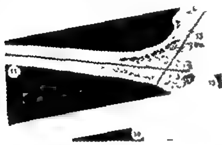

Fig. 7. (Film 1) frontal projection of the hip with the centre of the femoral head, the midaxis of the femoral neck and the proximal part of the longitudinal axis of the femur marked.

Fig. 8. (Film 2) lateral projection of the hip. The centre of the femoral head, the midaxis of the neck and the intersection between the axis of the proximal femur and the neck axis (point 21) are marked.

Fig. 9. (Film 3) lateral projection of the knee with a point, 31, on the longitudinal axis of the femur at the centre of the condylar mass.

In both projections the centre of the femoral head is relatively easily defined with the aid of a template with concentric circles. The projection of the centre of the femoral head on the films 1 and 2 is denoted by 13 and 22, respectively. The centre of the head is defined as the crossing point of the two lines through 13 and 22, respectively, and the corresponding foci.

In the frontal projection the axis of the femoral neck is readily defined as a straight line corresponding to the midline of the femoral neck and passing through the projection of the centre of the femoral head. This line is given by the point 13, as discussed above, and another point, 14, and it is used with both definitions of the axis of the femoral neck.

In the second example which is an indirect determination of an angle, we assume that the side l_1 is visible in both films and that its positive direction can be identified in film 2 We assume that the side l_2 is visible in film 1 but not in film 2, but that the projection P'' of a point P that is known to lie on the side l_2 is visible (fig 5) The positive direction of the line l_2 is assumed to correspond to the direction from the point of intersection of these lines (apex of the angle) to the point P With this information, an angle, denoted V_2, is uniquely defined

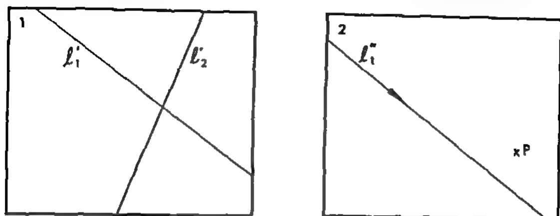

Fig 5

The angle V_2 can be determined as follows The point P can be determined as the point of intersection between the line P' F_2 and the plane $\Pi(F_1, l_2')$ This is equivalent to the above described indirect determination of a point The side l_1 is directly equivalent to definition of a line as discussed above, and the apex of the angle can be determined as the point of intersection Q between l_1 and the plane $\Pi(F_1, l_2')$ The other side, l_2 of the angle V_2 sought will then be given by the line Q P (fig 6)

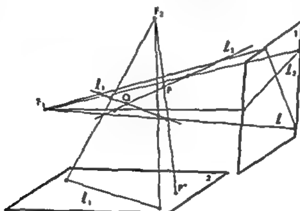

Fig 6

Definitions for determination of angles of the femoral neck

The determination of two femoral angles the anteversion and the inclination will be discussed

The method we have studied is based on examining the patient in the supine position with the femur horizontal and the lower leg hanging freely Three x ray projections are taken the frontal projection at the hip with vertical beam direction, the lateral projection at the hip and the lateral projection at the knee, both with horizontal beam direction Figures 7 – 9 show these three projections for a bone preparation positioned so as to correspond to the patient position described above For definitions of angles the long femoral axis was used The short proximal femoral axis can also be used but angles relating to this axis are not discussed in this paper

In frontal projection the femoral-diaphyseal axis is readily identified as the midline of the diaphysis, marked by the two points 11 and 12 In the lateral projection, however, the diaphysis is curved Two films are therefore used to determine the so called ideal shaft axis (Billing 1954) A point 21 is indicated in film 2 (fig 8) as the hypothetical point of intersection of the proximal extension of the midline of the diaphysis with the femoral neck and a point 31 in the midline of the condylar mass on the distal extension of the midline of the diaphysis (fig 9) The femoral diaphyseal axis is thereby determined The positive direction of the axis is defined as the direction from the hip to the knee

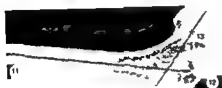

Fig. 7 (Film 1) frontal projection of the hip with the centre of the femoral head, the midaxis of the femoral neck and the proximal part of the longitudinal axis of the femur marked.

Fig. 8 (Film 2) lateral projection of the hip The centre of the femoral head, the midaxis of the neck and the intersection between the axis of the proximal femur and the neck axis (point 21) are marked

Fig. 9 (Film 3) lateral projection of the knee with a point, 31, on the longitudinal axis of the femur at the centre of the condylar mass.

In both projections the centre of the femoral head is relatively easily defined with the aid of a template with concentric circles The projection of the centre of the femoral head on the films 1 and 2 is denoted by 13 and 22, respectively The centre of the head is defined as the crossing point of the two lines through 13 and 22, respectively, and the corresponding foci

In the frontal projection the axis of the femoral neck is readily defined as a straight line corresponding to the midline of the femoral neck and passing through the projection of the centre of the femoral head This line is given by the point 13, as discussed above and another point, 14, and it is used with both definitions of the axis of the femoral neck.

In the second example which is an indirect determination of an angle, we assume that the side l_1 is visible in both films and that its positive direction can be identified in film 2. We assume that the side l_2 is visible in film 1 but not in film 2, but that the projection P ′ of a point P that is known to lie on the side l_2 is visible (fig. 5). The positive direction of the line l_2 is assumed to correspond to the direction from the point of intersection of these lines (apex of the angle) to the point P. With this information, an angle, denoted V_2, is uniquely defined.

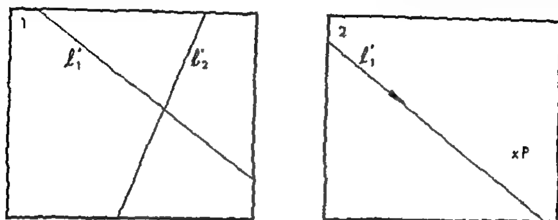

Fig. 5

The angle V_2 can be determined as follows. The point P can be determined as the point of intersection between the line $P'F_2$ and the plane $\Pi(F_1, l_2')$. This is equivalent to the above described indirect determination of a point. The side l_1 is directly equivalent to definition of a line as discussed above, and the apex of the angle can be determined as the point of intersection Q between l_1 and the plane $\Pi(F_1, l_2')$. The other side, l_2 of the angle V_2 sought will then be given by the line Q P (fig. 6).

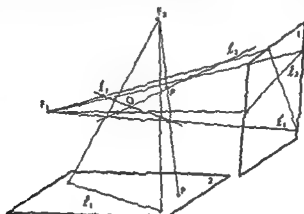

Fig. 6

Definitions for determination of angles of the femoral neck

The determination of two femoral angles, the anteversion and the inclination will be discussed.

The method we have studied is based on examining the patient in the supine position with the femur horizontal and the lower leg hanging freely. Three x ray projections are taken: the frontal projection at the hip with vertical beam direction, the lateral projection at the hip and the lateral projection at the knee, both with horizontal beam direction. Figures 7 – 9 show these three projections for a bone preparation positioned so as to correspond to the patient position described above. For definitions of angles the long femoral axis was used. The short proximal femoral axis can also be used but angles relating to this axis are not discussed in this paper.

ANTEV 1 corresponds to the anatomical direction of the axis of the femoral neck while ANTEV 2 corresponds to the angle of the direction to the centre of the femoral head seen in the longitudinal direction of the femur (fig 10)

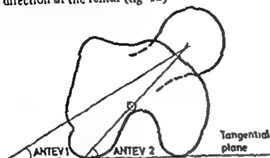

Fig. 10 A femur seen in axial direction from the knee with the two anteversion angles ANTEV 1 and ANTEV 2

A computer based method for measurement of angles

The x ray apparatus for which the method was developed is the Mimer III, but the method can, of course, be adapted for use with other similar devices

The Mimer III is so designed that the radiation source and the film in its cassette, which are firmly attached to each other, can be rotated around a horizontal axis and a vertical axis These axes of rotation pass through a point lying on the central ray which strikes the centre of the film (actually the centre of the aperture) at right angles to the film and is situated at a constant distance from the focus and the film plane The corresponding angles of rotation can be read off on scales. The radiation source film system can also be translated horizontally and this translation can also be measured For each film the two angles and the translation are noted The point of intersection of the central ray with the film can be determined as the centre of the rectangular image of the aperture This point is taken as the origin of a coordinate system on the film The directions of the axes of the coordinates are so chosen that one axis (the x axis) is parallel to the above described horizontal rotational axis The coordinate system established in this way is used for measuring points on the film (fig. 7 – 9) When the method is used for determination of the angle of a steel triangle two orthogonal projections are used For measurements on the femur a lateral projection of the knee is used in addition to two orthogonal projections over the hip (Fig 7 – 9) The slope of the condyle reference plane (tangential plane to the dorsal margin of the condyles) has been determined by fluoroscopy and read off on a graduated scale on the Mimer III In order to carry out the geometrical calculations necessary to be able to calculate angles in accordance with the above considerations from machine settings and coordinates measured on films two computer programs have been developed The programs are written in FORTRAN

The first program called ANGLE, can be used for determination of an angle that is directly visible and calculates the angle according to the two alternatives V_1 and V_2, which are defined previously

The second program called ANTEV, has been developed for measurements on the femur In this program the two anteversion angles ANTEV 1 and ANTEV 2 and the two angles of inclination CD 1 and CD 2 defined are calculated A mini computer PDP 11/40 was used for the calculations

The programs are generally applicable in that the x ray apparatus setting corresponding to the angles of rotation and the translation discussed above can be chosen arbitrarily for each individual film They should however, be chosen so that unfavourable projections in relation to the angle to be determined are avoided

Determination of the midaxis of the femoral neck in the lateral projection is a somewhat greater problem since it is rather difficult to define Two different definitions of the axis of the femoral neck have therefore been studied

In definition 1 of the axis of the femoral neck a line is drawn on film 2 through the projection of the centre of the femoral head and the middle of the femoral neck This line on film 2 is given by point 22 above and another point, 23 The axis of the femoral neck is then determined from its projections on films 1 and 2, corresponding to direct determination as discussed above With this definition it is not assumed that the midaxis of the femoral neck intersects the femoral diaphyseal axis This definition is in line with the anatomical conditions since the axis of the femoral neck for a normal femur is positioned in front of the proximal part of the femoral diaphysis, as pointed out by Norman (1969) In accordance with this definition of the axis of the femoral neck an inclination CD 1 is defined as the angle between this axis of the femoral neck and the femoral diaphyseal axis

It should be noted that the point 21 on film 2 is used only to determine the position of the femoral diaphyseal axis Errors in defining this point because of difficulty in defining the axis of the femoral neck will have relatively little influence on the femoral diaphyseal axis

Definition 2 of the femoral neck is indirect and dependent only on the midaxis of the femoral neck in the frontal projection The midaxis in the lateral projection is drawn only to construct the point 21 above The axis of the femoral neck is assumed in this case to intersect the femoral diaphyseal axis at a point O The point O is the intersection between the femoral diaphyseal axis, which is already determined, and the plane $\Pi(F_1, 13, 14)$ which passes through focus F_1 for film 1 and the points 13 and 14 on film 1 (fig 7) The axis of the femoral neck is thereby defined as the line through the point O and the centre of the femoral head The positive direction of the axis of the femoral neck is defined as the direction from O towards the centre of the femoral head

In accordance with this definition of the axis of the femoral neck we define an inclination CD 2 as the angle between the positive direction of this axis of the femoral neck and the positive direction of the angle of the femur

Every definition of an anteversion angle assumes a definition of a condyle reference plane parallel to the axis of the diaphysis This can be chosen in two ways One way is to let the reference plane pass through the axis of the condyle This is achieved by placing the patient in the horizontal position with his lower leg hanging freely, so that the direction of the reference plane at right angles to the axis of the diaphysis is horizontal

Another way is to let the condyle reference plane be the tangential plane to the dorsal parts of the condyles In this case the slope of the reference plane can be measured by fluoroscopy The angle can be read off on a graduated scale, when the central beam is tangential to the dorsal parts of the condyles (Norman 1969) This method was used in this study

The anteversion angle signifies the slope of the axis of the femoral neck towards the reference plane seen in the direction of the femoral diaphyseal axis The two definitions of the axis of the femoral neck discussed earlier correspond to two definitions of the anteversion angle ANTEV 1 and ANTEV 2 It should be noted that the two definitions of the anteversion angle represent two different angles (fig 10)

ANTEV 1 corresponds to the anatomical direction of the axis of the femoral neck while ANTEV 2 corresponds to the angle of the direction to the centre of the femoral head seen in the longitudinal direction of the femur (fig 10)

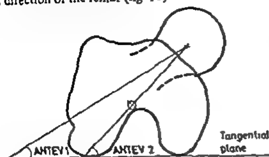

Fig. 10 A femur seen in axial direction from the knee with the two anteversion angles ANTEV 1 and ANTEV 2.

A computer-based method for measurement of angles

The x ray apparatus for which the method was developed is the Mimer III, but the method can, of course, be adapted for use with other similar devices

The Mimer III is so designed that the radiation source and the film in its cassette, which are firmly attached to each other, can be rotated around a horizontal axis and a vertical axis These axes of rotation pass through a point lying on the central ray which strikes the centre of the film (actually the centre of the aperture) at right angles to the film and is situated at a constant distance from the focus and the film plane The corresponding angles of rotation can be read off on scales. The radiation source film system can also be translated horizontally and this translation can also be measured For each film the two angles and the translation are noted The point of intersection of the central ray with the film can be determined as the centre of the rectangular image of the aperture This point is taken as the origin of a coordinate system on the film The directions of the axes of the coordinates are so chosen that one axis (the x axis) is parallel to the above described horizontal rotational axis The coordinate system established in this way is used for measuring points on the film (fig. 7 – 9) When the method is used for determination of the angle of a steel triangle, two orthogonal projections are used For measurements on the femur a lateral projection of the knee is used in addition to two orthogonal projections over the hip (Fig 7 – 9) The slope of the condyle reference plane (tangential plane to the dorsal margin of the condyles) has been determined by fluoroscopy and read off on a graduated scale on the *Mimer III* In order to carry out the geometrical calculations necessary to be able to calculate angles in accordance with the above considerations from machine settings and coordinates measured on films, two computer programs have been developed The programs are written in FORTRAN

The first program, called ANGLE, can be used for determination of an angle that is directly visible and calculates the angle according to the two alternatives V_1 and V_2, which are defined previously

The second program, called ANTEV, has been developed for measurements on the femur In this program the two anteversion angles, ANTEV 1 and ANTEV 2, and the two angles of inclination CD 1 and CD 2 defined are calculated A minicomputer PDP 11/40 was used for the calculations

The programs are generally applicable in that the x ray apparatus setting corresponding to the angles of rotation and the translation discussed above can be chosen arbitrarily for each individual film They should, however, be chosen so that unfavourable projections in relation to the angle to be determined are avoided

Determination of the midaxis of the femoral neck in the lateral projection is a somewhat greater problem since it is rather difficult to define Two different definitions of the axis of the femoral neck have therefore been studied

In definition 1 of the axis of the femoral neck a line is drawn on film 2 through the projection of the centre of the femoral head and the middle of the femoral neck This line on film 2 is given by point 22 above and another point, 23 The axis of the femoral neck is then determined from its projections on films 1 and 2, corresponding to direct determination as discussed above With this definition it is not assumed that the midaxis of the femoral neck intersects the femoral diaphyseal axis This definition is in line with the anatomical conditions since the axis of the femoral neck for a normal femur is positioned in front of the proximal part of the femoral diaphysis, as pointed out by Norman (1969) In accordance with this definition of the axis of the femoral neck an inclination CD 1 is defined as the angle between this axis of the femoral neck and the femoral diaphyseal axis

It should be noted that the point 21 on film 2 is used only to determine the position of the femoral diaphyseal axis Errors in defining this point because of difficulty in defining the axis of the femoral neck will have relatively little influence on the femoral diaphyseal axis

Definition 2 of the femoral neck is indirect and dependent only on the midaxis of the femoral neck in the frontal projection The midaxis in the lateral projection is drawn only to construct the point 21 above The axis of the femoral neck is assumed in this case to intersect the femoral diaphyseal axis at a point O The point O is the intersection between the femoral diaphyseal axis, which is already determined, and the plane $\Pi(F_1, 13, 14)$ which passes through focus F_1 for film 1 and the points 13 and 14 on film 1 (fig 7) The axis of the femoral neck is thereby defined as the line through the point O and the centre of the femoral head The positive direction of the axis of the femoral neck is defined as the direction from O towards the centre of the femoral head

In accordance with this definition of the axis of the femoral neck we define an inclination CD 2 as the angle between the positive direction of this axis of the femoral neck and the positive direction of the angle of the femur

Every definition of an anteversion angle assumes a definition of a condyle reference plane parallel to the axis of the diaphysis This can be chosen in two ways One way is to let the reference plane pass through the axis of the condyle This is achieved by placing the patient in the horizontal position with his lower leg hanging freely, so that the direction of the reference plane at right angles to the axis of the diaphysis is horizontal

Another way is to let the condyle reference plane be the tangential plane to the dorsal parts of the condyles In this case the slope of the reference plane can be measured by fluoroscopy The angle can be read off on a graduated scale, when the central beam is tangential to the dorsal parts of the condyles (Norman 1969) This method was used in this study

The anteversion angle signifies the slope of the axis of the femoral neck towards the reference plane seen in the direction of the femoral diaphyseal axis The two definitions of the axis of the femoral neck discussed earlier correspond to two definitions of the anteversion angle ANTEV 1 and ANTEV 2 It should be noted that the two definitions of the anteversion angle represent two different angles (fig 10)

$$\sigma^2 = \frac{\sum_{i}^{n}(V_i - V)^2}{n-1}$$

For certain positions of the steel triangle the angle is sensitive to changes in the measured variables Since the steel triangle was positioned arbitrarily, occasional measurement values showed relatively large deviation from the true value and this is reflected in the standard error In one case the value of 29 34° was obtained for the angle V_2 = 22 5°, with a theoretical error of measurement of 3 65°

When the method is used for practical purposes, standard positions are chosen so as to provide minimum sensitivity to errors of measured variables

A special series of 10 determinations was therefore performed on an angle of 45° in order to determine the reproducibility of measurements with slight changes of position of the steel triangle The mean values and corresponding standard errors for V_1 and V_2 are given in Table 2 The standard errors are considerably lower in this case

The tests with the metal angles thus gave an accuracy of measurement of 0 5° – 1°, provided that the angle was not placed in too adverse a position in relation to the directions of projection.

Determination of femoral angles

For determinations of femoral angles measurements have been carried out in a steel model of a femur and in a bone preparation The results are shown in tables 3 and 4 For measurements of steel models of the femur (table 3) the standard errors of anteversion angles exceed those for the corresponding inclination determined according to the method for direct visible angles by about 0 5° – 1° This difference is mainly explained by the fact that the slope of the condylar plane established by fluoroscopy was read off on a scale graduated in whole degrees, i e with a reading error of ± 0.5° A further source of error was the difficulty in aligning the tangential plane of the condyles during fluoroscopy Thus the condylar reference plane can not be determined with greater accuracy than ± 0.5° – 1° For the bone preparation the accuracy was less (table 4) This is natural since the difficulty in defining lines and points in an irregular anatomical object constitutes a further source of error over and above errors in determining the condylar reference plane

For anteversion angles an accuracy of about 3° was achieved and for inclination the accuracy was 1 5° – 2° for measurements on the femur preparation It seems that ANTEV 1 can be measured with somewhat greater accuracy than ANTEV 2

Comparison between theoretical and experimental errors of measurement

The calculated error of measurement, e_1, was compared with the statistical standard error in a number of experiments The values obtained are given in tables 1 – 4 It will be seen that the two types of errors are related The total error of measurement derives from two kinds of errors errors in measured variables and [illegible] measurement position, but for a [illegible] kinds of errors may be assumed [illegible] independent With the designation $e_{1,tot}$ for

Evaluation of the method

The reliability of the method has been investigated in two ways firstly, a theoretical calculation of the error based on the *computer based calculation* of angles, and, secondly, statistical estimation of the error, based on practical experiments with a number of series each comprising 10 determinations

Theoretical calculation of error

The computer program calculates four angles V_i, $i = 1, 2, 3, 4$ from a number of measured variables X_j, $j = 1, n$ $(n = 24)$ The resulting V_i are given functions $V_i = f_i(X_1, \quad , X_n)$ of the variables X_j Each measured variable is assumed to be associated with an error of measurement δ_j *We assume that these errors of measurement are statistically independent* The denotation 'partial error' is introduced for the quantity

$$e_{i,j} = f_i(X_1, \quad , X_j + \delta_j, \quad , X_n) - f_i(X_1, \quad , X_j, \quad , X_n)$$

This is an expression for how sensitive V_i is to errors in the variable X_j The program makes it possible to print out these errors, *which is of great value for analyses of the measurement technique* In accordance with Gauss' formula for the propagation of errors, the formula

$$e_i^2 = \sum_{j=1}^{n} e_{i,j}^2$$

for estimation of that part e_i *of the total standard error in* V_i *deriving from errors of measurement* in the variables X_j, is obtained The program provides automatic print-out of these calculated errors of measurement e_i for each calculated quantity V_i For errors of measurement in measured variables $\delta_i = 0\ 5$ mm is assumed for distances and $\delta_i = 0\ 5°$ for angles Tables 1 – 4 show the mean values for calculated theoretical errors

Experimental tests of reliability

A number of practical tests have been carried out using the method described, both as a check on its practical applicability and to determine the magnitude of the errors of measurement associated with this way of determining angles The experiments were divided into two parts In the first part the method was used to determine an angle defined as V_1 or V_2 above in a steel triangle In the second part the applicability of the method for determining different femoral angles was tested The measurements were carried out on a steel model of the femur and on a femur preparation Orthogonal projections were used in all cases and for measurements on the femur preparation the preparation was placed in a position corresponding to that in the description of the method

Determination of angles in a steel triangle

Three known angles 22 5°, 45° and 90° were each measured 10 times The triangles were positioned more or less arbitrarily for the individual measurements The calculations were carried out using the program ANGLE The results expressed as mean values and estimated values of the standard errors of the individual measurements are given in *table 1 The standard error of* the individual measurements was estimated according to the following formula

$$\sigma^2 = \frac{\sum_{1}^{n}(V_1 - V)^2}{n-1}$$

For certain positions of the steel triangle the angle is sensitive to changes in the measured variables Since the steel triangle was positioned arbitrarily, occasional measurement values showed relatively large deviation from the true value and this is reflected in the standard error In one case the value of 29 34° was obtained for the angle V_2 = 22 5°, with a theoretical error of measurement of 3 65°

When the method is used for practical purposes standard positions are chosen so as to provide minimum sensitivity to errors of measured variables

A special series of 10 determinations was therefore performed on an angle of 45° in order to determine the reproducibility of measurements with slight changes of position of the steel triangle The mean values and corresponding standard errors for V_1 and V_2 are given in Table 2 The standard errors are considerably lower in this case

The tests with the metal angles thus gave an accuracy of measurement of 0 5° – 1°, provided that the angle was not placed in too adverse a position in relation to the directions of projection.

Determination of femoral angles

For determinations of femoral angles measurements have been carried out in a steel model of a femur and in a bone preparation The results are shown in tables 3 and 4 For measurements of steel models of the femur (table 3) the standard errors of anteversion angles exceed those for the corresponding inclination determined according to the method for direct visible angles by about 0 5° – 1° This difference is mainly explained by the fact that the slope of the condylar plane established by fluoroscopy was read off on a scale graduated in whole degrees i.e with a reading error of ± 0.5° A further source of error was the difficulty in aligning the tangential plane of the condyles during fluoroscopy Thus the condylar reference plane can not be determined with greater accuracy than ± 0.5° – 1° For the bone preparation the accuracy was less (table 4) This is natural since the difficulty in defining lines and points in an irregular anatomical object constitutes a further source of error over and above errors in determining the condylar reference plane

For anteversion angles an accuracy of about 3° was achieved and for inclination the accuracy was 1 5° – 2° for measurements on the femur preparation It seems that ANTEV 1 can be measured with somewhat greater accuracy than ANTEV 2

Comparison between theoretical and experimental errors of measurement

The calculated error of measurement e_1 was compared with the statistical standard error in a number of experiments The values obtained are given in tables 1 – 4 It will be seen that the two types of errors are related The total error of measurement derives from two kinds of errors, errors in measured variables and errors intrinsic for the apparatus The dispersion depends on the measurement position, but for a given position the individual deviations arising from the two kinds of errors may be assumed to be statistically independent With the designation $e_{1\ tot}$ for

the total standard error and $e_{l, app}$ for the standard error from the apparatus, the following equation is then obtained

$$e^2_{l, tot} = e^2_l + e^2_{l, app}$$

The correlation between $e_{l, tot}$ and e_l in a series of experiments is shown in Fig 11 Theoretical estimation of $e_{l, app}$ is not possible It would seem fairly reasonable to assume, however, that $e_{l, app}$ is roughly proportional to e_l, which would give an approximative relationship of $e_{l, tot} = k \cdot e_l$ According to Fig 11, this seems consistent with a value of k of the order of 2 This indicates that the calculated error of measurement may be used to obtain a rough estimate of the total error for an individual reading

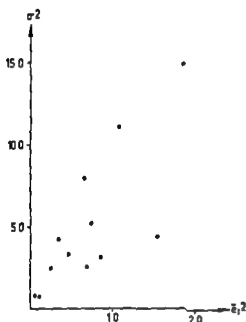

Fig 11 Twelve series of measurements, each comprising 10 determinations of anatomical angles in a femur preparation. σ = standard error in relation to the mean value obtained experimentally $\bar{e}_l$ = mean value for the theoretically calculated error of measurement There is a rough correlation between the two quantities σ and $\bar{e}_l$ (degrees)

the total standard error and $e_{1, app}$ for the standard error from the apparatus, the following equation is then obtained

$$e_{1, tot}^2 = e_1^2 + e_{1, app}^2$$

The correlation between $e_{1, tot}$ and e_1 in a series of experiments is shown in Fig 11 Theoretical estimation of $e_{1, app}$ is not possible It would seem fairly reasonable to assume, however, that $e_{1, app}$ is roughly proportional to e_1, which would give an approximative relationship of $e_{1, tot} = k \cdot e_1$ According to Fig 11, this seems consistent with a value of k of the order of 2 This indicates that the calculated error of measurement may be used to obtain a rough estimate of the total error for an individual reading

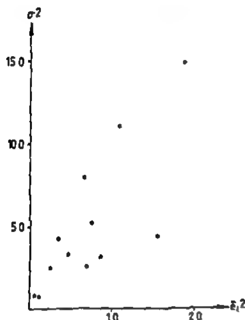

Fig 11 Twelve series of measurements each comprising 10 determinations of anatomical angles in a femur preparation. σ = standard error in relation to the mean value obtained experimentally $\bar{e}_1$ = mean value for the theoretically calculated error of measurement There is a rough correlation between the two quantities σ and $\bar{e}_1$ (degrees)

Table 1 Results (degrees) of measurements in steel angles arbitrarily positioned

Angle	Model	Mean value	Standard error (σ) in relation to mean value	Mean value ($\bar{e}_1$) of theoretical error of measurement
V_1	22 5	22 44	0 92	0 93
	45	44 95	0 42	0 54
	90	90 06	0 83	0 56
V_2	22 5	23 91	2 90	1 49
	45	45 29	0 96	0 54
	90	90 89	2 27	0 66

The error of measurement in axial tomographic determinations of the anteversion angle has been reported to be 2° – 3° (Hubbard & Staheli 1972) The method presented here does not assume in principle, any exact position in relation to the projection directions The projection directions need not be at right angles either As with Norman's method, distances are measured on the films, not angles Our determination of ANTEV 2, according to the above definition may be regarded as a generalization of Norman's method ANTEV 1, on the other hand, resembles most other methods and is based on marking the neck axis in two projections Although the femoral neck axis seems to be difficult to define in lateral projections ANTEV 1 seems to be associated with less error of measurement than ANTEV 2

All definitions of the anteversion angle assume a specified condylar reference plane Two such planes have been defined previously In both cases, the determination of the condylar reference plane is associated with errors of measurement of the order of 1°, which are directly reflected in the anteversion angle This is an inevitable source of error in all determinations of anteversion angles and is reflected in the fact that the standard error for anteversion angles is about one degree greater than for inclination

The essential difference between our method and conventional methods is a considerable generalization at the calculation stage i e conversion of points and lines on the film to final results in the form of anteversion and inclination It is based on similar physical measurement apparatus to that used in conventional methods and is therefore associated with essentially the same errors of measurement as are associated with this type of apparatus With the use of this type of apparatus and measurement procedure, an accuracy of about 0 5° – 1° would seem to constitute a lower limit for the accuracy of measurement The general computer based method of calculation allows simultaneous calculation of an arbitrary number of results and automatic estimation of the error The method used for determination of femoral angles here is also directly applicable to other anatomical measurements e.g determination of scoliosis angles.

Conclusions

1 A general computerized method for accurate determination of angles from roentgenograms has been established

2 The accuracy of measurement expressed as the standard error (SD) is ± 3° for anteversion and ± 2° for inclination

3 Several angles defined can be determined simultaneously together with theoretical estimations of the errors of measurement

4 The computerized method does not require an exact position of the object to be measured

Discussion

In direct measurements of given metal angles the present method has an accuracy of 0.5° – 1° These results are comparable with the control experiments in the monograph by Edholm (1966)

All the methods described for determination of anteversion presuppose a defined orientation of the diaphyseal axis of the femur in relation to one or both projections and the experiments on models have been performed under these conditions Most published reports on accuracy of measurement concern the biplanar methods (Dunlap et al 1953, Ryder & Crane 1953, Rippstein 1955) Dunlap et al carried out measurements on wooden models of the femur with wire axis and obtained variations up to 2° for the anteversion angle Rippstein found the error of measure ment to be of the same order in experiments with models These results largely accord with the error of measurement of 1 3° for the anteversion ANTEV 1 and 2 1° for the anteversion ANTEV 2 found in the present study in measurements on steel models of the femur Reports are lacking in the literature concerning measurements on femoral bones without indicators For the present method the standard error was found to be 3° when determining anteversion and 2° for inclina tion

Ruby et al (1979) who tested the Ryder Crane method found a standard error of 2 7° when measuring anteversion on bone models in which the transcondylar axis was identified by a steel wire which simplifies the determination of the plane of reference in the knee

In clinical use inadequate positioning of the femur renders further errors in the anteversion cal culated (Gross & Haike 1970) when using the biplanar methods The standard error of these methods has been found to be 5° in clinical practice (Ruby et al 1979) Ryder and Crane report ed that the directional error of the femoral axis could be as large as ± 10° These authors calcu lated that such an error gives a corresponding error of the anteversion of 10° This large error is of course, related to the method of measurement used in this technique Errors of this type have also been discussed by Dunlap et al and have been shown to be unacceptably large

A method in which the direction of the femoral axis is of less importance has been described by Norman (1965) Instead of measuring angles on the film, the distance from the centre of the fe moral head to the diaphyseal axis in the two projections is measured in two projections at right angles to one another If the distances are denoted by a_1 (lateral projection) and a_2 (frontal pro- jection), the anteversion angle is given by arctan $\frac{a_1}{a_2}$, which is then adjusted according to the slope of the femoral condylar plane This method assumes that the diaphyseal axis is parallel to either the horizontal or the sagittal film (not necessarily both) In the practical application of this method various magnification factors for the different projections owing to differences in distance between the centre of the femoral head and the film, may constitute a further source of error

A technique in which the anteversion angle is relatively independent of the direction of projec- tion has been described by Schultz (1924) and Budin & Chandler (1957) The femoral neck axis is projected here into a film plane at right angles to the longitudinal axis of the femur The ante version angle is read off directly as the slope of the femoral neck axis in relation to the femoral condylar plane In practice however it is difficult to identify the femoral neck axis in projec tions in the longitudinal direction of the femoral axis which limits the applicability of this direct method Arthrographic reproduction of the femoral head in the axial projection was used by Ed gren & Laurent (1956) Bernageau & Bourdon (1968) endeavoured to improve the reproduction by means of tomography

The error of measurement in axial tomographic determinations of the anteversion angle has been reported to be 2° – 3° (Hubbard & Staheli 1972) The method presented here does not assume, in principle, any exact position in relation to the projection directions The projection directions need not be at right angles either As with Norman's method, distances are measured on the films, not angles Our determination of ANTEV 2, according to the above definition, may be regarded as a generalization of Norman's method ANTEV 1, on the other hand, resembles most other methods and is based on marking the neck axis in two projections Although the femoral neck axis seems to be difficult to define in lateral projections, ANTEV 1 seems to be associated with less error of measurement than ANTEV 2

All definitions of the anteversion angle assume a specified condylar reference plane Two such planes have been defined previously In both cases, the determination of the condylar reference plane is associated with errors of measurement of the order of 1°, which are directly reflected in the anteversion angle Thus is an inevitable source of error in all determinations of anteversion angles and is reflected in the fact that the standard error for anteversion angles is about one degree greater than for inclination

The essential difference between our method and conventional methods is a considerable generalization in the calculation stage i e conversion of points and lines on the film to final results in the form of anteversion and inclination It is based on similar physical measurement apparatus to that used in conventional methods and is therefore associated with essentially the same errors of measurement as are associated with this type of apparatus With the use of this type of apparatus and measurement procedure, an accuracy of about 0 5° – 1° would seem to constitute a lower limit for the accuracy of measurement The general computer based method of calculation allows simultaneous calculation of an arbitrary number of results and automatic estimation of the error The method used for determination of femoral angles here is also directly applicable to other anatomical measurements e.g determination of scoliosis angles

Conclusions

1 A general computerized method for accurate determination of angles from roentgenograms has been established

2 The accuracy of measurement expressed as the standard error (SD) is ± 3° for anteversion and ± 2° for inclination

3 Several angles defined can be determined simultaneously together with theoretical estimations of the errors of measurement

ANATOMY AND GEOMETRY OF THE FEMUR PRACTICAL MEASURING METHOD

From the Department of Paediatric Radiology University of Goteborg Goteborg Sweden

Anatomy and geometry of the femur

The anatomy of the femur can be described by points axes and planes in the following way (fig 12) The longitudinal femoral axis forms a curved midline in the sagittal plane between point K and point O where K is the centre of the condylar axis and O is the point on the longitudinal axis of femur being at the shortest distance from the centre axis of the femoral neck The longitudinal axis of femur and the axis of the neck do not intersect each other At the proximal straight part of the femoral axis is point D The straight line OK is called the ideal shaft axis (Billing 1954) In the frontal view the centre axis of the femoral diaphysis can be considered straight

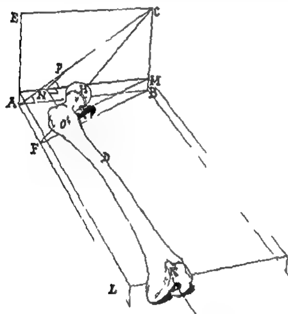

Fig 12 Perspective view of a femur with different axes and reference planes

The cross section of the femoral neck is almost circular in that part close to the head but changes laterally to a more elliptical shape (Backman 1957) The femoral head can be considered part of a sphere with centre H

The midaxis of the femoral neck is defined as a line through the centre of the head H and the geometrical centre of the neck i e the intersection of the short and long axes of the elliptical cross section of the femoral neck (line CHF in fig 12) A plane BAL is defined as the tangential plane to the femoral condyles parallel to the ideal axis The condylar axis of the knee through K is defined as parallel to the tangential plane BAL perpendicular to the ideal axis of the femur The plane AECB towards which the ideal axis of femur is perpendicular is used as a projection plane when determining the anteversion angles The direction of the projection is along the ideal axis This axis intersects the plane AECB in the point N The line HO connects the capital centre H with the point O on the longitudinal axis of the femur situated at the shortest distance from the centre axis of the femoral neck This line is projected as PN on plane AECB

The nomenclature is not uniform concerning the concepts anteversion and antetorsion. The most unambigous definitions were given by *Lange & Pitzen* (1921) who described anteversion as a turning of the neck and/or the head round an axis perpendicular to the plane BFC equivalent to a change of the angle BFC Torsion was defined as a rotation of the head and the neck round the longitudinal axis of femur and was defined as a change of the angle BAC

In cases where the femoral neck axis forms an angle dorsal to the frontal plane, the angles were called retroversion and retrotorsion respectively A correct use of these conceptions presupposes *that a change of the anteversion of the* antetorsion really has taken place and also a knowledge about which axis the rotation has occurred These facts are as a rule not known in the individual case Some authors (Johansson 1934 Dooley et al 1938, Laage 1953, Metz 1964, Konig 1972) have defined the angle BFC as the anteversion or the antetorsion angle However, most earlier authors defined anteversion or antetorsion as the angle BAC (Schultz 1924, Rogers 1931 and 1934, *Dunlap et al* 1953, Ryder & Crane 1953, Billing 1954 Rippstein 1955, Magilligan 1956, Budin & Chandler 1957, Backman 1957, Shands & Steele 1958, Reynolds & Herzer 1959, Hubbard & Staheli 1972)

The same angle is as a rule used in clinical practice in Scandinavia and we have found it natural to use this one Distinction between antetorsion and anteversion is not made in the following and the term anteversion will be used Henceforth we will call the angle BAC the anatomical anteversion of the femoral neck ANTEV 1 The angle of the projected femoral neck axis (PA in fig. 12) towards the frontal plane i.e the horizontal plane with the individual supine will be defined here as a functional anteversion and is denoted F ANTEV 1 (fig. 13)

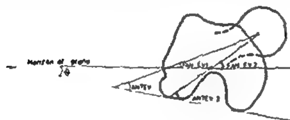

Fig 13 Axial view of the right femur with the angles of anatomical anteversion (ANTEV 1 and ANTEV 2) and functional anteversion (F ANTEV 1 and F ANTEV 2) Θ is the angle between the horizontal plane and the tangential plane to the dorsal parts of the femoral condyles

Norman (1969) has found when studying femoral preparations that the central axis of the femoral neck usually passes in front of the longitudinal axis of the femur To avoid calculation difficulties he defined the anteversion angle as the angle between the tangential plane of the femoral condyles and the line through the capital centre intersecting the longitudinal axis of the femur HO and projected on the plane AECB (PN in fig 12) This anatomical anteversion is here denoted ANTEV 2 (fig 13) The directional angle to the capital centre relative to the frontal plane of the body is called F ANTEV 2 (fig 13)

The rotation of the tangential plane to the condyles relative to the horizontal plane is given by the relations

$$\text{F ANTEV 1} - \text{ANTEV 1} = \theta$$
$$\text{F ANTEV 2} - \text{ANTEV 2} = \theta$$

($\Theta > 0$ outward rotation $\Theta < 0$ inward rotation)

Earlier authors either used the longitudinal axis of the femur KO or the short one when defining the inclination Our measurements refer to the angle CFL and HOK respectively in fig 12 and they are called CD1 and CD2. The line LA is parallel to the ideal axis KO

FEMORAL NECK ANTEVERSION AND INCLINATION IN NORMAL CHILDREN

In collaboration with Harald Asplund

From the Departments of Orthopaedic Surgery I and Paediatric Radiology, University of Göteborg, Göteborg, Sweden.

Introduction

When treating certain pathological conditions in the hip joint and the proximal femur it is necessary to know the magnitude of the anteversion angle as well as the inclination of the femoral neck. Determination of these angles is of great value when planning osteotomies in coxa plana and congenital hip dislocations and when forming an opinion on secondary changes of the hip caused by cerebral paresis or myelomeningocele. Many methods have been elaborated in order to measure these angles. However, it is hard to evaluate their reliability as studies regarding the error of method are often missing or are uncertain. This makes it impossible to determine the biological variation. Lack of precision regarding the anatomical definitions is a further source of error in many earlier works. Normal values based on roentgenological determination of the angles of anteversion and inclination have been published by Rogers (1934), Dunlap et al. (1953), Billing (1954), Shands & Steele (1958), Teintuner & Dechembre (1968) and Fabry et al. (1973). All these authors have found that the anteversion angle decreases with age, but the results are inconsistent regarding the magnitude of the anteversion angles at different ages. Measurements of anteversion angles have also been done on femur preparations taken from individuals of varying ages by among others Lange & Pitzen (1921), Kingsley & Olmsted (1948) and von Lanz (1951). However, the number of such investigations in children is small and the determinations of age is uncertain in the study of Kingsley & Olmsted.

We here report a study in children between the ages of three and sixteen. The method of measurement used has been described in chapter I and II.

Statistics

Standard statistical methods were used when calculating mean value, standard deviation, linear regression and covariance analysis. For tests of significance the quote of variance was calculated as follows

$$F = \frac{s^2 \text{ (due to regression)}}{s^2 \text{ (about regression)}}$$

Significant levels for found relations are accounted for with * for $p < 0.05$, ** for $p < 0.01$ and *** for $p < 0.005$

Fig 14 Arrangements for the lateral x ray of the femur

Practical measuring method

A Mimer III (Siemens–Elema) was used for the x ray examinations The child was placed supine with the femur horizontal and the lower leg hanging freely outside the edge of the examination table (fig 14) The trunk and pelvis were placed symmetrically without visible rotation Three x ray films were taken (24 x 30 cm), a frontal view of the hip, a horizontal lateral view of the hip after rotating down the tube 90° and a lateral view of the distal femur including the femoral condyles *This last film was exposed after horizontal translation of the tube and film* The rotation (Θ) of the dorsal parts of the femoral condyles towards the frontal plane was measured by fluoroscopy by angling the x-ray tube so that the posterior contours of the two femoral condyles coincided The angle was read off from the protractor of the x ray apparatus The calculation was done by the computer using the coordinates of the three films (chapter I, fig 7 – 9)

The following angles can be calculated

1 The anatomical anteversion of the femur (ANTEV 1) i e the angle between the projection of the middle axis of the femoral neck on plane AECB and the femoral condyle tangential plane (fig 12)

2 The functional anteversion of the femur (F ANTEV 1) i e the angle between the projection of the middle axis of the femoral neck on plane AECB and the frontal plane of the body

3 The anteversion angle according to Norman's definition (ANTEV 2) i e the angle between the projections on plane AECB of a line through the capital centre intersecting the ideal axis of the femur and the tangential plane to the femoral condyles

4 *The functional anteversion (F ANTEV 2) of the femur calculated according to 3 above*

5 The inclination with the same points of reference as in 1 and 3 above (CD1 and CD2)

6 ANTEV 1, F ANTEV 1, ANTEV 2 and F ANTEV 2 relative to the proximal axis of the femur (OD in fig 12)

It should be noted that when measuring according to 1 and 2 it is not assumed that the femoral neck axis intersects the longitudinal femur axis In these cases calculation of the shortest distance between the neck axis and the ideal femoral axis was included in the computer program

The sources of errors in this calculation of angles are principally limited to the x ray apparatus itself, to its adjustment and to the precision with which the points of reference can be identified on the x ray film The patient must also be lying totally still during the examination The error of measurement of the method is 2° – 3° (standard error) (chapter I) When measuring relative to the short proximal axis of the femur the error of method is 3° – 4° The doses of radiation at each examination were calculated with the assumption that the gonads were in the primary field when the two films of the hip-joint were exposed At the age of 4 the doses of radiation were calculated to 2 mGy, at the age of 7 to 3 mGy and at the age of 15 to 10 mGy

the same hip the following regression was found for the whole material ANTEV 1 = 0 84 ANTEV 2 r = 0 90 F = 14 4 p < 0 005 SD = ± 3.8°

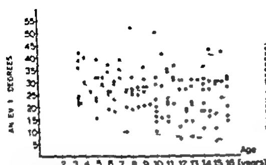

Fig. 15 Anatomical anteversion (ANTEV 1) in 123 normal children, 3 – 16 years old. The regression line and the ± 2 SD limits are marked.

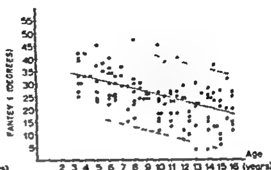

Fig. 16 Functional anteversion (F ANTEV 1) in 123 normal children 3 – 16 years old. The regression line and ± 2 SD limits are marked.

Anteversion and rotation of the femur

The angle of the femoral condylar tangential plane towards the frontal plane (Θ) of the individual forms a measure of the neutral rotation of the femur. With increasing age the neutral position is changed from relative outward rotation to relative inward rotation (fig 17) which explains the difference between functional and anatomical anteversion.

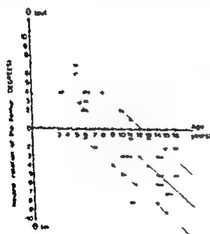

Fig 17 The neutral rotation (Θ) of the femur in 123 children 3 – 16 years old. The regression line and the ± 1 SD limits are marked. The frontal plane of the body is the plane of reference and positive angles (Θ) mean outward rotation from this plane and negative angles inward rotation.

Material

123 children (70 boys, 53 girls) from 3 to 16 years were examined Children were chosen who had been referred for radiological examination with suspicion of fracture of the leg and in whom no fracture was found at the radiography Children with a history of previous hip injury or hip disease were excluded All measurements concern the right femur as there is no support in the literature about asymmetry of the hips in healthy individuals However, during this investigation Cyvin (1977) reported on asymmetry of anteversion in normal children An additional series consisting of 10 healthy children was therefore measured bilaterally There was no significant difference between the two sides concerning anteversion and inclination in this investigation. The angles of the tangential planes to the condyles had a difference between right and left side of ≤ 3°

The results are presented in table 5 (page 29) and the following differences between right and left hips were obtained (means ± SD)

ANTEV 1 = 0 5° ± 4 4°
CD 1 = – 1 3°± 2 3° no significant difference
ANTEV 2 = –0 6° ± 5 7°
CD 2 = –1 7° ± 4 0°

Results

Anteversion angles

The values of the angles defined in chapter II were measured for each child The results are presented in table 7 (page 30) The linear regressions are presented in table 6 (page 29)

There is a decrease (*) in anteversion (ANTEV 1) with age in the whole material (fig 15) Regression analysis of ANTEV 1 demonstrates that in girls the average value decreases (*) from 34° at the age of 3 to 23° at the age of 16 For boys the angles are 27° and 22° respectively This decrease is not significant Girls have higher anteversion than boys of the same age (*) The average value of regression for the functional anteversion F ANTEV 1 is 34° at the age of 3 and 17° at the age of 16 (***) Boys and girls are presented together as there is no significant difference between them (fig 16)

ANTEV 2 does not vary significantly with age in either boys or girls Also here girls have higher anteversion than boys (*) The functional anteversion, F ANTEV 2, like F ANTEV 1, has no significant difference between boys and girls There is a decrease (***) with age, as for F ANTEV 1, from 36° at the age of 3 to 23° at the age of 16

ANTEV 1 and F ANTEV 1 using the short proximal femoral axis have also been calculated The results are not presented here as the variation is somewhat greater than using the long ideal axis

The biological standard deviation (Biol SD) for the different anteversion angles has been estimated from the relation $(\text{Biol SD})^2 = (\text{Total SD})^2 - (\text{Method error})^2$ ANTEV 1 (girls) = 9 4°, ANTEV 1 (boys) = 7 7°, F ANTEV 1 = 6 9°, ANTEV 2 (girls) = 9 1°, ANTEV 2 (boys) = 8 5° and for F ANTEV 2 = 7 4°

The middle axis of the femoral neck has been found to pass ventrally to the longitudinal axis of the femur The shortest distance between the two axes is separated from 0 (***) The shortest distance of the femoral neck axis to the ideal axis increases with age from 1 7 mm at the age of 3 – 4 to 4 2 mm at the age of 15 – 16 When comparing the values of ANTEV 1 and ANTEV 2 for

the same hip the following regression was found for the whole material ANTEV 1 = 0 84 ANTEV 2 r = 0 90 F = 14 4 $p < 0.005$ SD = ± 3 8°

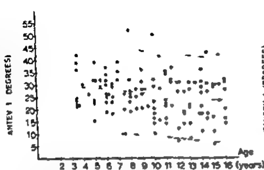

Fig. 15 Anatomical anteversion (ANTEV 1) in 123 normal children 3 – 16 years old The regression line and the ± 2 SD limits are marked.

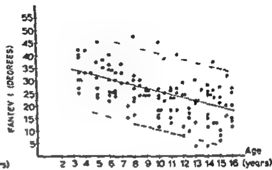

Fig 16 Functional anteversion (F ANTEV 1) in 123 normal children 3 – 16 years old The regression line and ± 2 SD limits are marked

Anteversion and rotation of the femur

The angle of the femoral condylar tangential plane towards the frontal plane (Θ) of the individual forms of a measure of the neutral rotation of the femur With increasing age the neutral position is changed from relative outward rotation to relative inward rotation (fig 17) which explains the difference between functional and anatomical anteversion

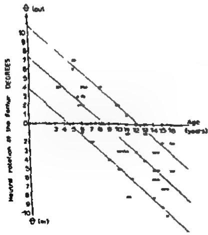

Fig 17 The neutral rotation (Θ) of the femur in 123 children 3 – 16 years old The regression line and the ± 1 SD limits are marked. The frontal plane of the body is the plane of reference and positive angles (Θ) mean outward rotation from this plane and negative angles inward rotation.

To elucidate the connection between anatomical anterversion and the neutral position of the femur in rotation those individuals whose neutral position differs more than ± 1 SD from the average value of regression of the age class (fig 17) were chosen These children's anatomical anteversion angles are accounted for in fig 18, where the average value of regression for Antev 1 for boys and girls are also marked Children with relative inward neutral rotation have an anatomical anteversion angle above the average and children with relative outward neutral rotation have an anatomical anteversion angle below the average

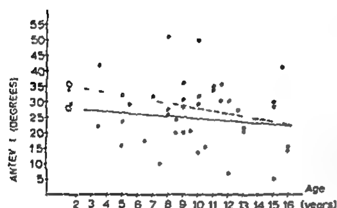

Fig 18 The anatomical anteversion (ANTEV 1) of individuals with an inward neutral rotation (○) or outward (●) > 1 SD from the mean value of the age group are compared The regression line for ANTEV 1 relative to age in girls and boys divides the two groups in the diagram

If correlation is also made for the age factor the relation between the neutral rotation of the femur (Θ), the angle of anatomical anteversion and age can be described as

ANTEV 1 $\Theta = 13\ 2 - 0\ 94\ \text{age} - 0\ 20\ \text{ANTEV 1}$
$r = 0\ 78,\ F = 91\ 21,\ p < 0\ 005$

ANTEV 2 $\Theta = 12\ 9 - 0\ 87\ \text{age} - 0\ 18\ \text{ANTEV 2}$
$r = 0\ 77,\ F = 88\ 12,\ p < 0\ 005$

Angles of inclination

Regression analysis demonstrates that both CD 1 and CD 2 diminish somewhat with age (*) CD 1 from 137° at 3 years of age to 131° at 16 years of age and CD 2 from 135° to 131° No significant difference between boys and girls was found The equations of regression are given in *table 6*

The biological variation for CD 1 is 5 8° and for CD 2 6 0°

Discussion

Methods for determining the angles of anteversion and inclination depend on precise anatomical definitions The longitudinal axis of the femur should be defined as the ideal axis of the femur to avoid unreliability of measurement due to bending of the femur in the sagittal plane In comparable measurements we have found a somewhat greater variation of anteversion angle if the short proximal axis of the femur is used instead of the ideal axis and also a higher numerical value of the angle because of the mentioned bending

As Norman (1969) we have found that the central axis of the femoral neck passes in front of the longitudinal axis of the femur The anteversion defined by Norman (ANTEV 2) thus gives higher values than ANTEV 1 (fig 12) In clinical practice measuring according to Norman s definition is easy and the method of choice The regression found ANTEV 1 0 84 ANTEV 2 implies that the values achieved well reflect the anteversion of the femoral neck i e ANTEV 1

The major drawback in earlier studies is the lack of a well defined plane of reference in the distal femur to which the angles of the femoral neck axis can be related. Previous authors have determined the femoral condylar tangent either by palpation of the medial and lateral joint spaces (Konig & Schult 1973) or defined the tangent as perpendicular to the longitudinal axis of the lower leg where the knee joint as a rule has been kept bent 90° (Dunlap et al 1953 Ryder & Crane 1953

angulation of the lower leg in 10° valgus or varus without any contemporary rotation of the femur (Brattstrom 1962) We have therefore used the method described by Norman (1969) where the direction of the femoral condylar tangent is determined by fluoroscopy when determining the distal plane of reference The anatomical anteversion is a measure of the rotational position of the femoral neck and head in relation to the tangential plane of the femoral condyles (fig. 12) This measure can be used when calculating malrotations in femoral fractures (chapter V)

The functional anteversion is a compound measure of the anatomical anteversion and of the neutral position of the femur in rotation This angle can together with the anatomical anteversion give information on imbalance in rotation of the hip joint in neuromuscular disorders such as cerebral palsy myelomeningocele and polio The existing difference between anatomical and functional anteversion has not been payed attention to by earlier authors

The radiographically determined normal values (Rogers 1934 Dunlap et al 1953 Billing 1954 Shands & Steele 1958 Fabry et al 1973) demonstrate a marked decrease of the anteversion with increasing age in close agreement with the variation in the functional anteversion in our material As earlier authors have not taken into account that the condylar reference plane rotates inward with increasing age their results therefore mainly describe a functional anteversion Fabry et al. (1973) has reported a S D for anteversion in his normal material which closely corresponds to our S D for F ANTEV 1 Lanz has measured the angle of anteversion in femur preparations irrespective of sex On the whole this author used the same points of reference as in our calculation of ANTEV 1 ANTEV 1 for the whole material has the same relation to age as reported by v Lanz with a decrease of the angle of anteversion by 10° from 4 to 16 years of age We have found that girls however seem to have higher anatomical anteversion than boys at a given age. This difference was also reported by Cyvin (1977)

To elucidate the connection between anatomical anterversion and the neutral position of the femur in rotation those individuals whose neutral position differs more than ± 1 SD from the average value of regression of the age class (fig 17) were chosen These children's anatomical anteversion angles are accounted for in fig 18, where the average value of regression for Antev 1 for boys and girls are also marked Children with relative inward neutral rotation have an anatomical anteversion angle above the average and children with relative outward neutral rotation have an anatomical anteversion angle below the average

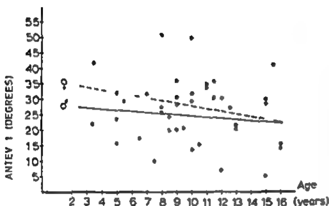

Fig 18 The anatomical anteversion (ANTEV 1) of individuals with an inward neutral rotation (○) or outward (●) > 1 SD from the mean value of the age group are compared The regression line for ANTEV 1 relative to age in girls and boys divides the two groups in the diagram

If correlation is also made for the age factor the relation between the neutral rotation of the femur (Θ), the angle of anatomical anteversion and age can be described as

ANTEV 1 $\Theta = 13\,2 - 0\,94$ age $- 0\,20$ ANTEV 1
$r = 0\,78, F = 91\,21, p < 0\,005$

ANTEV 2 $\Theta = 12\,9 - 0\,87$ age $- 0\,18$ ANTEV 2
$r = 0\,77, F = 88\,12, p < 0\,005$

Angles of inclination

Regression analysis demonstrates that both CD 1 and CD 2 diminish somewhat with age (*) CD 1 from 137° at 3 years of age to 131° at 16 years of age and CD 2 from 135° to 131° No significant difference between boys and girls was found The equations of regression are given in table 6

The biological variation for CD 1 is 5 8° and for CD 2 6 0°

Discussion

Methods for determining the angles of anteversion and inclination depend on precise anatomical definitions The longitudinal axis of the femur should be defined as the ideal axis of the femur to avoid unreliability of measurement due to bending of the femur in the sagittal plane In com parable measurements we have found a somewhat greater variation of anteversion angle if the short proximal axis of the femur is used instead of the ideal axis and also a higher numerical value of the angle because of the mentioned bending

As Norman (1969) we have found that the central axis of the femoral neck passes in front of the longitudinal axis of the femur The anteversion defined by Norman (ANTEV 2) thus gives higher values than ANTEV 1 (fig 12) In clinical practice measuring according to Norman's defi- nition is easy and the method of choice The regression found ANTEV 1 = 0 84 ANTEV 2 im plies that the values achieved well reflect the anteversion of the femoral neck i e ANTEV 1

The major drawback in earlier studies is the lack of a well defined plane of reference in the distal femur to which the angles of the femoral neck axis can be related Previous authors have deter mined the femoral condylar tangent either by palpation of the medial and lateral joint spaces (Konig & Schult 1973) or defined the tangent as perpendicular to the longitudinal axis of the lower leg where the knee joint as a rule has been kept bent 90° (Dunlap et al 1953, Ryder & Cra ne 1953, Billing 1954 Rippstein 1955, Magilligan 1956, Budin & Chandler 1957, Shands & Steele 1958 Gibson 1967) The palpation of the tibia is an unreliable indicator of the direction of the femoral condylar tangent With the knee flexed 90° the collateral ligaments often permit an angulation of the lower leg in 10° valgus or varus without any contemporary rotation of the femur (Brattstrom 1962) We have therefore used the method described by Norman (1969) where the direction of the femoral condylar tangent is determined by fluoroscopy when deter mining the distal plane of reference The anatomical anteversion is a measure of the rotational position of the femoral neck and head in relation to the tangential plane of the femoral condyles (fig. 12) This measure can be used when calculating malrotations in femoral fractures (chapter V)

The functional anteversion is a compound measure of the anatomical anteversion and of the neutral position of the femur in rotation This angle can together with the anatomical anteversion give information on imbalance in rotation of the hip joint in neuromuscular disorders such as cerebral palsy myelomeningocele and polio The existing difference between anatomical and functional anteversion has not been payed attention to by earlier authors

The radiographically determined normal values (Rogers 1934, Dunlap et al 1953, Billing 1954, Shands & Steele 1958, Fabry et al 1973) demonstrate a marked decrease of the anteversion with increasing age, in close agreement with the variation in the functional anteversion in our material. As earlier authors have not taken into account that the condylar reference plane rotates inward with increasing age, their results therefore mainly describe a functional anteversion Fabry et al (1973) has reported a S.D for anteversion in his normal material which closely corresponds to our S.D for F ANTEV 1 Lanz has measured the angle of anteversion on femur preparations ir respective of sex On the whole this author used the same points of reference as in our calculation of ANTEV 1 ANTEV 1 for the whole material has the same relation to age as reported by v Lanz with a decrease of the angle of anteversion by 10° from 4 to 16 years of age We have found that girls however seem to have higher anatomical anteversion than boys at a given age This difference was also reported by Cyvin (1977)

Crane (1959) observed that children with pronounced toeing in and toeing out had a high and a low anteversion angle respectively This is in line with our data Crane, however, drew the conclusions that the extreme anatomical anteversion angles were caused by the fact that these children prefer sitting like frogs or tailors respectively In extreme cases this may be the explanation Similar conditions exist in cerebral palsy (Samilson 1975) However, when the anteversion angle is within ± 2 SD of the normal, presence of toeing in and toeing out might be caused by the above mentioned functional adjustment

The trivariate linear relation of regression between neutral position of the femur in rotation, anatomical anteversion and age of the individual summarizes the normal anatomical and functional development of the torsion or version of the femur and neutral rotation during growth Beals (1969) and Fabry et al (1973) amongst others have shown that the angle of anteversion in children with cerebral palsy and congenital dislocation of the hip is higher than in normal children Other authors (Alvik 1950, Morscher 1967) have proposed that a high anteversion angle is connected with a higher incidence for coxarthrosis The above mentioned trivariate linear relation may be useful in further studies of these conditions

We have measured the inclination using the ideal axis of the femur Strasser (1917), v Lanz & Wachsmuth (1938) and Shands & Steele (1958) have determined this angle using the proximal part of the femoral diaphysis (OD in fig 12) Determination using the ideal axis gives somewhat larger angles but the difference is very small as observed by Billing (1954) Our measurements indicate that the inclination decreases somewhat with age coinciding with earlier radiological investigations (Heinrich et al 1968, Zippel 1971, Hamacher 1974) The average values of CD 1 and SD in this study are almost identical with Zippel's results (1971) However, we could not find any significant difference between boys and girls In adulthood our and Zippel's values are consistent with the values given by Backman (1957), who made measurements on femur preparations from adults

Conclusions

This radiographic study of anteversion and inclination of the femoral neck in normal children has demonstrated that

1 The anatomical anteversion of the femoral neck decreases slightly with age at least in girls while the functional anteversion decreases considerably in both sexes because of the fact that the neutral position of the femur in rotation changes from relative outward rotation to relative inward rotation with increasing age

2 Both anatomical and functional anteversion have a wide biological variation ± 2 SD is about $15^\circ - 20^\circ$

3 High anatomical anteversion is compensated for by relative inward rotation and low anatomical anteversion by relative outward rotation of the neutral position of the femur

4 The inclination of the femoral neck decreases slightly with increasing age

5 Measurement of anteversion according to Norman accurately reflects the angle between the femoral neck and the condylar plane

A FOLLOW-UP STUDY OF CHILDREN WITH CONGENITAL DISLOCATION OF THE HIP TREATED WITH VON ROSEN SPLINT IN THE NEONATAL PERIOD

In collaboration with Goran Hansson and Bertil Romanus

From the Departments of Orthopaedic Surgery II and Paediatric Radiology, University of Goteborg, Goteborg, Sweden

Introduction

It is possible to diagnose congenital dislocation of the hip (CDH) in the neonatal period and the chance of successful therapy increases if the treatment is started immediately (von Rosen 1956, Palmén 1961, Barlow 1962, Fredensborg 1975)

Increased anteversion of the femoral neck has been reported by several authors to be part of the anatomical derangement in CDH (Badgley 1943, Edgren & Laurent 1956, Shands & Steele 1958, Fabry et al 1973)

Increased anteversion of the femoral neck has also been proposed to be a factor predisposing to osteoarthrosis of the hip joint (Alvik 1960, Morscher 1967, Muller 1971)

Alvik (1960) recommended operation with derotation osteotomy at the proximal end of the femur in children with increased anteversion of the femoral neck as a single sign of dysplasia

Fredensborg (1975) reported on 111 children with CDH treated with von Rosen splint for 3 months He evaluated the results obtained by measuring the centre-edge angle (CE angle – Wiberg 1939) and the spherical index (Fredensborg 1975) and classified all except 2 children as normal

Cyvin (1977) on the other hand reported on increased angles of anteversion of the femoral neck when re examining 129 children with CDH who had been treated with the Frejka pillow in the neonatal period (Frejka 1941)

The purpose of this follow up investigation was to study the anteversion and inclination of the femoral neck in children at the age of 6 – 9 years treated with the von Rosen splint during the neonatal period because of unstable hips (CDH)

The angles of anteversion (ANTEV 1 and ANTEV 2) (fig 19) and inclination of the femoral neck (CD 1) have been measured by the technique defined in chapter I and II The standard error of this method has been determined to be 3° when measuring angles of anteversion and 2° when measuring inclination With a standard error of 3° when measuring anteversion the SD of difference in anteversion between normal symmetrical hips is $SD = \sqrt{3^2 + 3^2} \approx 4\ 25°$ and $2\ SD \approx 8\ 5°$ Additionally the centre-edge angle (CE angle – Wiberg 1939) was measured as well as the spherical index introduced by Fredensborg (1975)

The roentgenograms were also evaluated by an independent radiologist

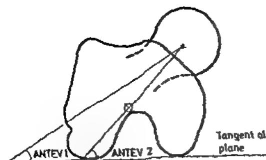

Fig 19 Axial view of the right femur seen in the direction of the long ideal axis with the 2 antever sion angles ANTEV 1 and ANTEV 2

Material

Between 1968 and 1970 there were 19 259 live births in the two departments of obstetrics in Gothenburg. 482 children (326 girls and 156 boys) with suspected unstable hips were referred to the Department of Orthopaedic Surgery within the first 10 days of life 125 children demon strated on clinical examination by the orthopaedic surgeons unstable hips (Ortolani 1937, Pal mén 1961 Barlow 1962) Twenty-eight of these 125 children were selected (22 girls and 6 boys) for this study Only children where the clinical diagnosis of hip instability was well documented were included (Hansson & Romanus 1975) No distinction was made between dislocatable and dislocated hip joints

Primary clinical assessment

Eleven girls with unstable hips had unilateral and 11 had bilateral hip instability when first ex amined (table 8) Four of the 6 boys with unstable hips had unilateral and 2 had bilateral hip in stability when first examined (table 8)

Table 8 Unstable hips at primary clinical assessment

	Left hip	Right hip	Bilateral	Total
Girls	5	6	11	22
Boys	2	2	2	6
Total	7	8	13	28

Choice and length of abduction treatment

All children had abduction treatment with the von Rosen splint, 4 cases less than 6 weeks, 15 cases between 6 – 9 weeks and 9 cases more than 9 weeks (table 12) Primary abduction treat ment with the von Rosen splint was followed by a period of abduction treatment with Frejka pillow in all cases except 3 Total abduction time varied between 9 – 29 weeks (table 12)

Statistics

Standard statistical methods were used, Fischer's test for pair-wise comparisons and Student's t test The statistical significance (p) was tested at the 0 05 level

A FOLLOW-UP STUDY OF CHILDREN WITH CONGENITAL DISLOCATION OF THE HIP TREATED WITH VON ROSEN SPLINT IN THE NEONATAL PERIOD

In collaboration with Goran Hansson and Bertil Romanus

From the Departments of Orthopaedic Surgery II and Paediatric Radiology, University of Goteborg, Goteborg Sweden

Introduction

It is possible to diagnose congenital dislocation of the hip (CDH) in the neonatal period and the chance of successful therapy increases if the treatment is started immediately (von Rosen 1956 Palmén 1961, Barlow 1962, Fredensborg 1975)

Increased anteversion of the femoral neck has been reported by several authors to be part of the anatomical derangement in CDH (Badgley 1943, Edgren & Laurent 1956, Shands & Steele 1958 Fabry et al 1973)

Increased anteversion of the femoral neck has also been proposed to be a factor predisposing to osteoarthrosis of the hip joint (Alvik 1960, Morscher 1967, Muller 1971)

Alvik (1960) recommended operation with derotation osteotomy at the proximal end of the femur in children with increased anteversion of the femoral neck as a single sign of dysplasia

A FOLLOW-UP STUDY OF CHILDREN WITH CONGENITAL DISLOCATION OF THE HIP TREATED WITH VON ROSEN SPLINT IN THE NEONATAL PERIOD

In collaboration with Goran Hansson and *Bertil Romanus*

From the Departments of Orthopaedic Surgery II and Paediatric Radiology, *University of Gote borg*, Goteborg Sweden

Introduction

It is possible to diagnose congenital dislocation of the hip (CDH) in the neonatal period and the chance of successful therapy increases if the treatment is started immediately (von Rosen 1956 Palmén 1961, Barlow 1962, Fredensborg 1975)

Increased anteversion of the femoral neck has been reported by several authors to be part of the anatomical derangement in CDH (Badgley 1943, Edgren & Laurent 1956, Shands & Steele 1958, *Fabry et al* 1973)

Increased anteversion of the femoral neck has also been proposed to be a *factor predisposing to osteoarthrosis of the hip joint (Alvik 1960, Morscher 1967, Muller 1971)*

Alvik (1960) recommended operation with derotation osteotomy at the proximal end of the fe mur in children with increased anteversion of the femoral neck as a single sign of dysplasia

Fredensborg (1975) reported on 111 children with CDH treated with von Rosen splint for 3 *months He evaluated the results obtained by measuring the centre-edge angle* (CE-*angle* – Wi berg 1939) and the spherical index (Fredensborg 1975) and classified all except 2 children as normal

Cyvin (1977) on the other hand reported on increased angles of anteversion of the femoral neck when re examining *129 children with CDH* who had been treated with the Frejka pillow in the neonatal period (Frejka 1941)

The purpose of this follow up *investigation was to study the anteversion* and inclination of the femoral neck in children at the age of 6 – 9 years treated with the von Rosen splint during the neonatal period because of unstable hips (CDH)

The angles of anteversion (ANTEV 1 and ANTEV 2) (fig 19) and inclination of the femoral neck (CD 1) have been measured by the *technique defined in chapter I and II The standard error of* this method has been determined to be 3° when measuring angles of anteversion and 2° when measuring inclination With a standard error of 3° when measuring anteversion the SD of differ ence in anteversion between normal *symmetrical hips is* $SD = \sqrt{3^2 + 3^2} \approx 4\ 25^\circ$ and $2\ SD \approx 8\ 5^\circ$ Additionally the centre edge angle (CE angle – Wiberg 1939) was measured as well as the spherical index introduced by Fredensborg (1975)

The roentgenograms were also evaluated by *an independent radiologist*

Comparison of unstable hips and hips in normal children

1 Anteversion measured [redacted] ANTEV 1 and ANTEV 2 was within the limit of ± 2 SD for the reference material consisting of 123 hips (chapter III) except in 1 unstable hip measured as ANTEV 1 and in 3 hips measured as ANTEV 2 (figures 20 – 21) The inclination was within the ± 2 SD in 39 of 41 unstable hips (fig 22)

Girls and boys are represented in different diagrams The anteversion was measured at the age of 6 – 9 years and compared with the anteversion of 123 normal children in the reference material (70 boys and 53 girls) represented by the regression mean and ± 2 SD limits.

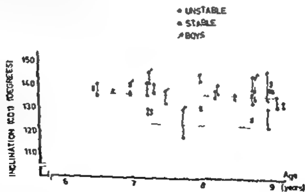

Fig 22 The inclination values (CD 1) in right and left hips in 28 children with unstable hips at birth. Girls and boys are represented together The regression mean and ± 2 SD limits for the reference material of 123 normal children are included for comparison.

Results

The results obtained are presented in table 12 (page 40)

Conventional radiographic evaluation In 7 children (8 hips) the findings were considered as pathological (shallow acetabulum, short femoral neck and/or horizontal epiphyseal plate) and 5 children (9 hips) were judged as having a valgus deformity (table 12)

CE angles were all ⩾ 15° except for one child (13°) and the spherical index was > 0 36 in all children (table 12)

Measurements of anteversion (ANTEV 1 and ANTEV 2) and inclination (CD 1)

a. Children with unilateral hip instability (n = 15)

No difference between unstable and stable hips was found regarding angles of ANTEV 1, ANTEV 2 and CD 1 (*table 9*)

Table 9 Mean value and SD of anteversion and inclination (degrees) in children with unilateral hip instability (n = 15)

Angle	Unstable hip	Stable hip	Difference unstable – stable hip	p
ANTEV 1	31 ± 6 8	28 ± 5 3	2 9 ± 7 8	>0 05
ANTEV 2	38 ± 8 4	33 ± 11 9	4 4 ± 10 6	>0 05
CD 1	135 ± 5 0	135 ± 5 9	0.3 ± 5 7	>0 05

b Children with bilateral hip instability (n = 13)

No difference between right and left hip was found in children with bilateral hip instability re garding the angle of ANTEV 1, ANTEV 2 and CD 1 (table 10)

Table 10 Mean value and SD of anteversion and inclination (degrees) in children with bilateral hip instability (n = 13)

Angle	$\frac{dx + sin}{2}$	dx – sin	p
ANTEV 1	31 ± 8 0	3 0 ± 8 0	>0 05
ANTEV 2	37 ± 9 1	2 9 ± 8 2	>0 05
CD 1	135 ± 6 4	–1 ± 3 8	>0 05

When comparing children with unilateral and bilateral hip instability regarding the angles ANTEV 1, ANTEV 2 and CD 1, no significant difference was found

There was no correlation between anteversion of the femoral neck (ANTEV 1) and length of ab duction treatment

version is greater than the functional anteversion This means that the children with reported increased anteversion in Cyvin's study might have a still higher anteversion if measured relative to the femoral condyles

The results of our investigation support the idea that it is necessary to choose a more rigid form of immobilization of the hip joints to obtain normal angles of anteversion When comparing our experiences with those of Cyvin, it must be pointed out that he included children with neurological disorders and there have been earlier reports on increased anteversion without dislocation of the hip joints in children with cerebral paresis (Beals 1969, Fabry et al 1973)

There is no evidence of asymmetrical anteversion in healthy children [Norman 1978, Asplund & Henriksson (chapter III)] Cyvin (1977) reported on asymmetrical development of anteversion of the femoral neck in 28 % of the children with unstable hips Seven out of 28 children in this study (4 with bilateral hip instability and 3 with unilateral hip instability) had a difference in the angles of anteversion (ANTEV 1 and ANTEV 2) between right and left hip of 9° or more indicating asymmetrical development In 2 out of 3 children with unilateral hip instability the anteversion was higher on the unstable side

When interpreting the AP films of the pelvis there was an impression of valgity in 5 children (9 hips) The inclination calculated was, however, within normal limits (135° – 146°)

This study has shown that in children with CDH the anteversion and inclination are within normal limits However the conventional radiological evaluation demonstrated abnormalities, such as horizontal tilting of the epiphyseal plate (fig 23) and shortening of the femoral neck These changes will be the subject for further studies

Fig. 23 X ray of the right and left hip in a child (patient no 20 female, 7 years) treated with von Rosen splint in the neonatal period because of unstable right hip At the examination a marked epiphyseal tilting was found on the right side with a short femoral neck. Left hip normal.

Conclusions

In studying 28 children (22 girls and 6 boys) with unstable hips treated with the von Rosen splint during the neonatal period, the following results were obtained

1 In children with CDH there were no differences between stable and unstable hips with regard to anteversion and inclination

2 The measured angles of unstable hips did not differ from those of healthy children of the same age

3 The length of abduction treatment did not influence the angle of anteversion of the femoral neck

4 Minor disturbances in development of the hip joints were seen

2 12 girls and 27 boys in the reference material (chapter III) were of the same age as the children with unstable hips (5 5 – 9 5 years) (table 7)

When comparing the anteversion and the inclination (ANTEV 1, ANTEV 2) in 22 girls with unstable hips with 12 girls with normal hips of the same age, no statistical difference was found The same result was found when comparing inclination (CD 1) Nor was there a difference between 6 boys with unstable hips and 27 boys with normal hips of the same age (table 11)

Table 11 Angles of anteversion and inclination (degrees) in 28 children with unstable hips and 39 children with normal hips

Angle	Girls		Boys	
	Unstable n = 22	Normal n = 12	Unstable n = 6	Normal n = 27
ANTEV 1	31 ± 6 3	31 ± 7 4	31 ± 10 7	26 ± 7 0
ANTEV 2	38 ± 7 4	37 ± 7 8	38 ± 13 0	29 ± 8 1
CD 1	135 ± 5 0	134 ± 10 4	136 ± 9 9	136 ± 4 7

Discussion

There have been several reports of failures when treating children with unstable hips during the neonatal period with different kinds of splints (Hiertonn & James 1968, Fellander et al 1970, Walker 1971, Williamson 1972, Bjerkreim 1974, Cyvin 1977) Several reports have also been presented on iatrogenic effects of abduction treatment in children with CDH (Little et al 1960, Dooley 1964, Salter et al 1969, Gage & Winter 1972, Gore 1974) The opinions therefore vary about the type of abduction treatment that should be used Salter et al (1969) postulated that the adverse effects seen by abduction treatment depend on trauma to the blood vessels of the femoral head He stressed the importance of not forcing the femoral head into the acetabulum and recommended the use of Frejka pillow postulating "The hips are not rigidly immobilized yet maintained in a stable position This type of splint is particularly useful for the newborn infants " According to Hiertonn & James (1968) it is necessary to choose a more rigid fixation of the hip joints and they recommend the use of the von Rosen splint

This investigation has shown normal anteversion and inclination in children with unstable hips treated with the von Rosen splint during the neonatal period and these results are to be compared with the reports on increased anteversion in children treated with the Frejka pillow during the neonatal period (Bjerkreim 1974, Cyvin 1977) Eriksson & James (1970) also found a tendency to increased angles of anteversion in children treated with unspecified splint for unstable hips during the neonatal period However, the number of patients in their study was too small for statistical evaluation The anteversion measured by Cyvin, Eriksson & James was the angle between the femoral neck and the frontal plane, i e a functional anteversion This functional anteversion was also studied by Asplund & Henriksson (chapter III) who demonstrated that, when the anteversion is above average there is usually an inward rotation of the tangential plane to the dorsal part of the femoral condyles, i e when the anteversion is high the anatomical ante

version is greater than the functional anteversion This means that the children with reported increased anteversion in Cyvin s study might have a still higher anteversion if measured relative to the femoral condyles

The results of our investigation support the idea that it is necessary to choose a more rigid form of immobilization of the hip joints to obtain normal angles of anteversion When comparing our experiences with those of Cyvin it must be pointed out that he included children with neurological disorders and there have been earlier reports on increased anteversion without dislocation of the hip joints in children with cerebral paresis (Beals 1969 Fabry et al 1973)

There is no evidence of asymmetrical anteversion in healthy children [Norman 1978 Asplund & Henriksson (chapter III)] Cyvin (1977) reported on asymmetrical development of anteversion of the femoral neck in 28 % of the children with unstable hips Seven out of 28 children in this study (4 with bilateral hip instability and 3 with unilateral hip instability) had a difference in the angles of anteversion (ANTEV 1 and ANTEV 2) between right and left hip of 9° or more indicating asymmetrical development In 2 out of 3 children with unilateral hip instability the anteversion was higher on the unstable side

When interpreting the AP films of the pelvis there was an impression of valgity in 5 children (9 hips) The inclination calculated was however within normal limits (135° – 146°)

This study has shown that in children with CDH the anteversion and inclination are within normal limits However the conventional radiological evaluation demonstrated abnormalities such as horizontal tilting of the epiphyseal plate (fig 23) and shortening of the femoral neck These changes will be the subject for further studies

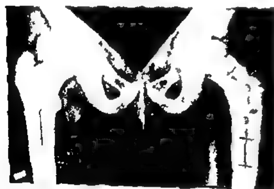

Fig. 23 X-ray of the right and left hip in a child (patient no 20 female 7 years) treated with von Rosen splint in the neonatal period because of unstable right hip At the examination a marked epiphyseal tilting was found on the right side with a short femoral neck. Left hip normal.

Conclusions

In studying 28 children (22 girls and 6 boys) with unstable hips treated with the von Rosen splint during the neonatal period the following results were obtained

1 In children with CDH there were no differences between stable and unstable hips with regard to anteversion and inclination.

2 The measured angles of unstable hips did *not differ* from those of healthy children of the same age

3 The length of abduction treatment did *not influence* the angle of anteversion of the femoral neck

4 Minor disturbances in development of the hip joints were seen

A FOLLOW-UP STUDY OF CHILDREN WITH FEMORAL FRACTURES

In collaboration with Harald Asplund and Bjorn Henrikson

From the Departments of Orthopaedic Surgery I, Paediatric Surgery and Paediatric Radiology, University of Goteborg, Göteborg, Sweden

Introduction

Femoral shaft fractures in children have a natural tendency to heal and conservative treatment with traction is therefore the usual mode of therapy. Some spontaneous correction of angular deformity occurs during the healing process (Vontobel et al 1961, Weber 1969), but not of malrotation It has been claimed that these malrotations may play an important part in the develop ment of arthrosis of the hip and knee (Muller 1967) It has also been pointed out that clinical symptoms occur when the torsion exceeds 20° (Nicod 1967) Torsion alters the anteversion in the hip and Muller considers that anteversion of more than 30° and retroversion of the neck of the femur by more than 5° causes arthrosis of the hip In order to avoid this, corrective osteotomy has been recommended (Vontobel et al 1961, van Joost & Gastkemper 1972, Zenker 1972) For determination of the degree of torsion in the fracture both clinical (Kootstra 1973, van Joost & Gastkemper 1972) and radiological methods have been used The radiological methods are based on measurement of the difference in anteversion between the healthy and the fractured side, usually by means of the methods proposed by Dunlap et al (1953) and Rippstein (1955) Measurements performed in this way assume that both the knee joints and the femur are symmetrically positioned when the lower legs are symmetrically positioned, conditions which are difficult to achieve during clinical measurement The error of measurement in clinical practice is therefore difficult to evaluate The above mentioned authors, as well as Hamacher (1974), have estimated the error of measurement in clinical practice to be 5° – 10° As pointed out by Norman (1969) knowledge of the orientation of the knee joint is necessary for reliable measure ments of the angle of anteversion With a measuring error of 5° with the Rippstein method a difference of 5° between the fractured and non fractured side as proposed by Benum et al (1979) does not necessarily indicate a torsion of the same degree

With the Rippstein method differences of 10° – 15° between right and left side can appear when measuring the anteversion of normal hips Ruby et al (1979) reported such differences when using the Ryder-Crane method, which is a similar biplanar method

The aim of this study is to assess the torsion in healed femoral shaft fractures using a method in which the methodological error is known (chapter I and II) The dislocation of the fractures, especially the torsion, has been compared with the childrens' clinical symptoms and signs

Determination of the torsion presupposes a knowledge of the original anatomy Since this is dif ficult to obtain from ordinary roentgenograms it is natural to compare with the contralateral side In normal children there is no evidence of asymmetry between right and left hip (Norman 1978, and chapter III) Thus we define the torsion as the difference in anteversion between the non fractured and the fractured sides (fig 24) Since the femoral shaft has been fractured, the

None of the 4 fractures with increased anteversion on the fracture side, i e indicating inward torsion, exhibited a greater difference than 5° in anteversion

The 4 fractures fixed by osteosynthesis all had smaller torsion than 5° Since the surgical procedure allowed restitution of symmetrical anatomy, and thus essentially the same anteversion bilaterally, the measurements in these 4 cases may be regarded as a control of the accuracy of measurement, i e original symmetry between right and left

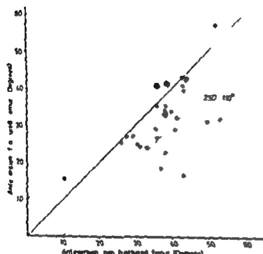

Fig 25 The degree of torsion in 28 femoral fractures. Each point represents the anteversion in one patient for the femur on the fractured and non fractured side. ○ denotes AO synthesis of four femoral fractures The limit for variation in the error of measurement is indicated in the diagram with 2 SD = ± 10°

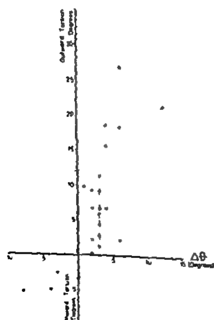

Fig 26 The relationship between the fracture torsion and the difference in inclination from horizontal of the condylar planes on the fractured and non fractured sides ΔΘ, is illustrated. ΔΘ is usually positive owing to reduced anteversion on the fractured side. ΔΘ is < 0 if the fracture has caused increased anteversion on the fractured side. When ΔΘ < 3° the torsion was < 12°

long, ideal shaft axis from the knee to the proximal femur (Billing 1954) has not been used The anteversion was therefore determined relative to the proximal short straight axis of the femur

The anteversion was measured according to Norman (1969) and is defined as the direction angle of the capital centre relative to the tangential plane of the femoral condyles, as seen in the direction of the short axis (fig 24)

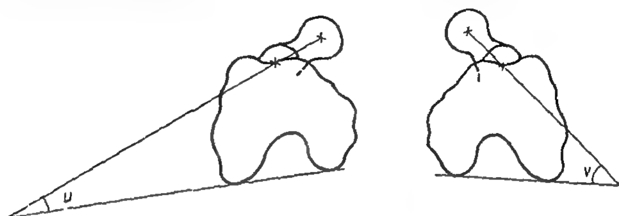

Fig 24 The fractured (right) and non fractured (left) femur in the axial projection. The line through the centre of femoral head and axis of the shaft of the femur forms an anteversion angle u and v, respectively, with the condylar plane Torsion v – u

The radiological examination was performed as described in chapter II, with the patient placed supine with the pelvis horizontal and the lower leg hanging freely on the side to be investigated The tangential plane of the dorsal parts of the condyles of the knee was determined on both sides by fluoroscopy and read off on the scale of the x ray apparatus The measurement errors in model experiments for this method of determining the angle of anteversion relative to the short proximal axis are 3 5° and are thus negligibly greater than when the ideal axis is used (Blomberg & Henriksson, chapter I) The SD for difference between symmetrical right and left hip is $\sqrt{3\,5^2 + 3\,5^2} \approx 5°$ $2\,SD \approx 10°$

Material

The follow up investigation comprises 28 children with consecutive unilateral femoral shaft fractures (14 boys and 14 girls) Their ages ranged between 5 and 16 years, the mean age being 9 5 years The interval between the occurrence of the fracture and the investigation varied between 2 months and 4 years Of the 28 fractures 24 were treated with traction Twenty of these 24 fractures were situated in the central part of the shaft, 2 in the proximal part and 2 in the distal part The remaining 4 fractures were treated by osteosynthesis according to the AO method Three of these fractures were situated in the central part of the shaft and one in the distal part

Results

Radiological measurement of the angle of anteversion

In 21 of the 24 fractures treated with traction the anteversion was reduced on the fractured side (fig 25) i e indicating outward torsion of the distal fragment of the femur However in only 6 cases the outward torsion of the distal fragment was greater than 2 SD for the methodological error

Table 13 demonstrates the torsions classified by transverse and oblique fractures The material is too small to allow conclusions about whether different fracture surfaces are associated with differences in the degree of torsion No difference could be detected Four of the 6 fractures with outward malrotation of > 10° had a moderate varus angulation The two remaining fractures were oblique fractures without visible dislocation from the axis In 10 cases of 12 without varus or valgus dislocation the torsion was < 10° Valgus dislocation was uncommon in this material 5 cases In 3 of these 5 cases there was a tendency to slight inward torsion (fig 27)

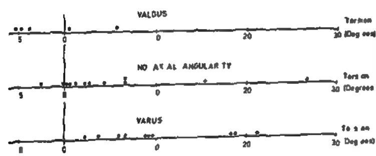

Fig 27 Torsion for different axial dislocation (varus valgus and non axial dislocation) The axial dislocation has been assessed from the frontal projection of the femur when the fracture has healed

Clinical investigation

No evidence of asymmetric gait could be found in any child Clinical classification into small and large torsions was not possible In children found radiologically to have small malrotations (< 10°) no evidence of a difference in the capacity for inward and outward torsion of the hips was found but such a difference was found in some children with large torsions

Four children had subjective symptoms The study has not given any indications that the subjective symptoms can be explained by the torsion in the fracture, except in one case – a 16 year old girl with a malrotation of 18°. The subjective symptoms four years after the fracture consisted of a feeling of tautness in the front of the thigh, clicking in the right ankle during gait and difficulty in running one year after the fracture occurred The patient walks well without limping and can sit on her haunches and run. The other three children with subjective symptoms had torsion of < 10° In two of these three cases the subjective symptoms could be explained by pain in the knees owing to concomitant patellar fractures These two children also had difficulty in sitting on their haunches

Discussion

Like Yano & Sawada (1975) we have found that conservative treatment of femoral fractures with traction in children usually causes outward torsion of the distal fragment The total frequency of outward torsion is higher in our study than has previously been reported (Yano & Sawada 1975, Piroth & Bliesener 1977). Yano & Sawada, who used Rippstein's method of measurement, reported three cases of inward torsion of > 15° among 31 cases. Even allowing for a standard error of measurement of 5° with Rippstein's method, the occurrence of inward torsion must be regarded as proven. In one case they found an inward torsion of 20 – 25° The frequency of large outward torsion (> 15°) in our study (20 %) is essentially consistent with the figure of 25 % found by the above authors, with 30° as the upper limit for outward torsion. However, outward torsion after traction may sometimes be as great as about 40° (Probst 1977)

The torsions after AO synthesis were small, as found in previous studies (Kootstra 1973).

No difference in torsion between transverse and oblique fractures was detected The study suggests, however, that outward torsion is associated with moderate varus dislocation, at least in cases of large malrotations This association has not previously been reported Varus and valgus dislocations correct spontaneously less often than ad latus dislocations (Vontobel et al 1961)

Since the femur, including the distal fragment, is curved in the lateral projection, an outward torsion of the distal fragment may give the impression of varus in the frontal projection. This may be one explanation why varus dislocation appears to be associated with large outward torsion.

No clear connection between subjective symptoms and gait disturbances owing to torsion has been found in this study The incidence of subjective symptoms was strikingly low and was not related to torsion In two of the four children with subjective symptoms the symptoms could be explained by concomitant patellar fractures The torsion in these cases was slight Only in one case were the symptoms considered to be due to the torsion. This patient had an outward torsion of 18° and experienced a feeling of tautness in the front of her thigh and moderate pain and clicking in her ankle Symptoms of this type have been reported in connection with torsion (van Joost & Gastkemper 1972 Kootstra 1973)

Retroversion of > 5° is considered to cause coxarthrosis in adulthood (Müller 1967) In our study all outward malrotations were less than the anteversion on the contralateral side This means that symmetry between the right and left knee during forward gait does not cause retroversion on the fracture side The lower limit of torsion as an indication for corrective osteotomy varies. Zenker (1972) gives a limit of 30° and Vontobel *et al.* (1961) propose a figure of 15° for outward torsion For inward malrotation the same authors propose 5 – 10° At present we do not consider that there are clear indications for osteotomy in our material The possibility of subjective symp-

Retroversion of > 5° is considered to cause coxarthrosis in adulthood (Muller 1967) In our study all outward malrotations were less than the anteversion on the contralateral side This means that symmetry between the right and left knee during forward gait does not cause retroversion on the fracture side The lower limit of torsion as an indication for corrective osteotomy varies Zenker (1972) gives a limit of 30° and Vontobel et al (1961) propose a figure of 15° for outward torsion For inward malrotation the same authors propose 5 – 10° At present we do not consider that there are clear indications for osteotomy in our material The possibility of subjective symp-

toms occurring later must be borne in mind, however, since the duration of follow up in this study is only a few years

Since clinical assessment of torsions appears to be difficult, a simple method of estimating the angle of anteversion is desirable if subjective symptoms and gait disturbances occur An associ ation between anteversion and condylar tangent inclination has been demonstrated by Asplun & Henriksson (chapter III) High anteversion at a certain age is associated with relative inward rotation of the condyle of the knee and low anteversion with outward rotation The results shown in fig 26 are in line with this association and suggest a method of screening The positi of the condyle of the knee with the patient in the supine position with the pelvis horizontal c be determined by fluoroscopy If there is an obvious difference between the inclinations of th condylar tangents, marked torsion in the fracture is usually present Complete radiological measurement of the angle of anteversion should be carried out If, on the other hand, the incli nations of the condyles of the knees are found by fluoroscopy to be essentially symmetric, tor sion is unlikely to be present and further radiological investigation can be avoided

Conclusions

Torsion in fractures of the femoral shaft in children treated by traction have been evaluated by radiological measurement of anteversion The clinical and subjective symptoms have then been compared with the torsion

1 Outward torsion of the distal fragment is more common than inward torsion

2 *In cases with outward torsion a concomitant moderate varus angulation was often found*

3 A method of screening is proposed for determining whether concomitant torsion is present in the fracture in cases with subjective symptoms and gait disturbances

GENERAL DISCUSSION

A general computer based method for determination of anatomical angles from roentgenograms was developed This method is especially designed for determination of anteversion and inclination of the femoral neck In this investigation a MIMER III apparatus was used but measurements can be performed with similar devices In principle the measurement set up is identical to that described by Norman (1969) The x ray exposures are performed with the child in a constant supine position and the lower leg hanging freely Three films are exposed for each leg – a frontal and a lateral view of the hip and a third view of the knee The main difference from Norman's method is the use of a computer in the processing of the measured data from the films By the three films the orientation of the femur is defined relative to a coordinate system From coordinates on the films of the axes and points of the femur the angles are calculated by mini computer The computer program (ANTEV in FORTRAN) is based on the general principles for central projection In contrast to all other previously described methods the present computerized method does not presuppose an exactly defined position of the patient

The first comparison between different principal methods for the determination of anteversion with regard to comparative accuracy and reproducibility as well as the radiation dose to the gonads has recently been presented by Ruby et al (1979)

They made experiments in models and evaluated the results in clinical measurements Three methods were compared The fluoroscopic (Rogers 1934), the biplanar (Ryder & Crane 1953) and the axial (Dunn 1952) In clinical use the accuracy of measurement, expressed as the standard error (SD) was found to be within ± 5° for all three methods They recommended the biplanar method because it was also easy to use in children with spasticity and this method was found to give the least radiation to the gonads Another similar biplanar method was introduced by Rippstein (1955)

The Rippstein and the Ryder–Crane methods are performed in essentially the same way The only difference is the abduction for the second projection (Rippstein 20°, Ryder–Crane 30°) Two films are exposed

1 AP projection of the hips in neutral position
2 AP projection of the neutrally rotated hips in a position of 90° flexion and 20° or 30° of abduction (γ°)

In the two films the projection CD' of the true inclination CD and the projection AV' of the true anteversion AV are constructed and measured (fig 28) The true angle of anteversion is then calculated from the formula

$$\tan(AV) = \tan(AV) \cdot \frac{\cos(CD - 90^\circ - \gamma)}{\cos(CD - 90^\circ)}$$

Rippstein used a conversion table based upon this formula

For a correct understanding of the values achieved in clinical use the standard error of the measuring method must be considered The errors in clinical practice must exceed the experimental and theoretical limit

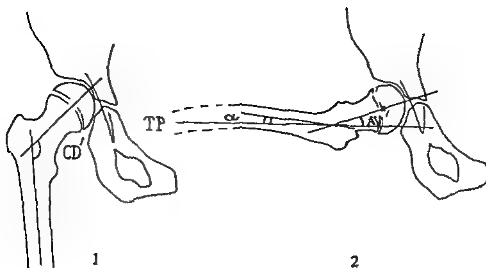

Fig 28 1 Frontal projection of the right hip 2 Projection of the right hip after flexion and abduction. The projected angle of the inclination (CD') The projected anteversion (AV') Transverse plane (TP) The angle between the proximal shaft of the femur and the transverse plane (α)

Various factors contribute to the final error of the method

A Construction and measurement of angles on the films

B Orientation of the patient e g

1 *Asymmetric positioning*

2 *Inexact abduction of the legs.*

3 *Determination of the plane of reference at the knees*

C Instability of the x ray apparatus

The influence of errors in A and B upon the accuracy of measurement of the biplanar methods can be estimated theoretically

Theoretical estimation of errors

Construction and measurement of angles on the films

On the assumption that the patient is symmetrically positioned according to the definition for the biplanar methods above, a theoretical calculation of errors can be performed in the following way

By applying the Gaussian formula for propagation of errors

$$|\delta AV|^2 = \sum_{i=1}^{3} \left(\frac{\partial AV}{\partial V_i}\right)^2 (\delta V_i)^2$$

$V_1 = AV$, $V_2 = CD'$, $V_3 = \gamma$ (abduction) to the formula for AV above, partial errors from these variables

$$\frac{\partial AV}{\partial AV'} \cdot \delta AV' \quad \frac{\partial AV}{\partial CD'} \cdot \delta CD \quad , \quad \frac{\partial AV}{\partial \gamma} \cdot \delta\gamma$$

and the total error δAV can be calculated from errors in the 3 variables δAV, $\delta CD'$ and $\delta\gamma$ respectively

In the calculations an error of 1° ($\delta AV' = \delta CD = \delta\gamma = 1°$) has been assumed for the 3 variables. Five measurements according to the Rippstein method performed and illustrated with roentgenograms by Cyvin (1977) were used by the present author for the calculations representing high, medium and low anteversion AV (table 14)

Table 14 Results (degrees) of 5 measurements with the Rippstein method ($\delta AV' = \delta CD' = \delta\gamma = 1°$ assumed) Calculated partial errors $\frac{\partial AV}{\partial AV'} \cdot \frac{\partial AV}{\partial CD} \cdot \frac{\partial AV}{\partial \gamma}$ and the total error δAV are given in the table.

AV	AV'	CD'	$\frac{\partial AV}{\partial AV'} \cdot 1$	$\frac{\partial AV}{\partial CD'} \cdot 1$	$\frac{\partial AV}{\partial \gamma} \cdot 1$	δAV
67	43	168	0 72	1 11	0.57	1 44
63	48	158	0 82	0 55	0 44	1 67
38	28	148	1 17	0 40	0.38	1 30
25	20	136	1 20	0 21	0 19	1 23
17	13	141	1.31	0 18	0 17	1.33

An error in the variables AV, CD' and γ of 1° gives a theoretical error $\delta AV \leq 1.5° - 2°$ in the anteversion AV. The sensitivity is greatest to an error in AV'. An error in AV' of 1° gives an error of about 1° $\left(\frac{\partial AV}{\partial AV'} \cdot 1°\right)$ in all cases

The sensitivity to CD and abduction is smaller than for AV. The sensitivity to these variables is most marked in high anteversion where an error of 1° gives an error of 0 5° – 1° in the calculated [illegible]

[illegible]

values in the table 5 times larger

When the anteversion is high unreliable results have been found by Elsasser & Walker (1973), who hold that the formula for AV is not precise for high anteversions. As a result of the theoretical considerations above this opinion can be modified. The formula is correct, but can be sensitive to the variables measured

The computerized method for determination of angles presented in chapter I is a similar biplanar method. The rotation of the x ray tube for the lateral exposure of the hip corresponds to an abduction $\gamma = 90°$. Although the computerized method uses coordinates instead of angles on the films, the sensitivity of the calculated anteversion and inclination to errors in construction and measurement on the films as found theoretically in chapter I are comparable to the sensitivity of the biplanar methods discussed

In order to relate the results obtained by theoretical calculations to experimental and clinical results for the biplanar methods, it is necessary first to estimate realistic values of errors in the measured variables AV and CD and secondly to take into account other sources of errors not accounted for in the formula for AV

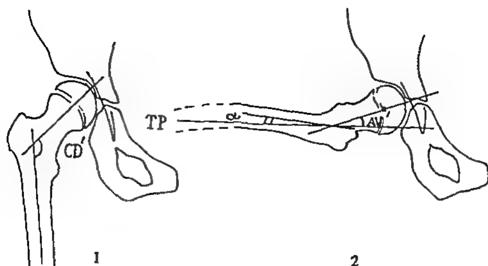

Fig 28 1 Frontal projection of the right hip 2 Projection of the right hip after flexion and abduction. The projected angle of the inclination (CD') The projected anteversion (AV') Transverse plane (TP) The angle between the proximal shaft of the femur and the transverse plane (α)

Various factors contribute to the final error of the method

A Construction and measurement of angles on the films

B Orientation of the patient e g

1 *Asymmetric positioning*

2 *Inexact abduction of the legs.*

3 *Determination of the plane of reference at the knees.*

C Instability of the x ray apparatus

The influence of errors in A and B upon the accuracy of measurement of the biplanar methods can be estimated theoretically

Theoretical estimation of errors

Construction and measurement of angles on the films

On the assumption that the patient is symmetrically positioned according to the definition for the biplanar methods above, a theoretical calculation of errors can be performed in the following way

By applying the Gaussian formula for propagation of errors

$$|\delta AV|^2 = \sum_{i=1}^{3} \left(\frac{\partial AV}{\partial V_i}\right)^2 (\delta V_i)^2$$

$V_1 = AV'$, $V_2 = CD'$, $V_3 = \gamma$ (abduction) to the formula for AV above, partial errors from these variables

$$\frac{\partial AV}{\partial AV'} \cdot \delta AV' \quad \frac{\partial AV}{\partial CD'} \cdot \delta CD' \ , \ \frac{\partial AV}{\partial \gamma} \cdot \delta\gamma$$

determination of the inclination of the condyles by fluoroscopy According to the results in chapter I the plane of reference can be determined with an accuracy of about ± 0 5° – 1° Measurement relative to well-defined planes of reference at the knee has contributed to a better understanding of the variation of anteversion during childhood (chapter III)

The sources of error discussed including the instability of the x ray apparatus add to the final result given by the Gaussian formula for propagation of errors A standard error of at least 5° therefore seems reasonable when using a biplanar method clinically which is in accordance with the values found by Ruby et al

Interpretation of clinical measurements

The evaluation of a change in anteversion is usually based on a comparison with the contra lateral side assuming an original symmetry in normal individuals With a standard error of 5° the SD of differences in anteversion between normal right and left hips is $SD = \sqrt{5^2 + 5^2} \approx 7°$ and 2 SD ≈ 14° Such differences were found by Ruby et al when they measured normal hips with the biplanar method The largest difference was 16° No statistically significant asymmetry was found between normal right and left hips which is in accordance with our results (chapter III) In the follow up study of CDH (chapter IV) the possibilities of symmetrical or asymmetrical development of anteversion have been discussed

Torsion can be measured in femoral fractures the torsion being defined [redacted] the difference in anteversion between the nonfractured and the fractured sides (chapter V)

Benum et al (1979) proposed that a difference of 5° in anteversion between the hips could in dicate a torsion in the previously fractured femur The theoretical calculations and the experi ments presented by Ruby et al demonstrate that a difference of 5° with the biplanar methods [redacted] too small to state that torsion exists

Torsion after previously traction treatment of femoral shaft fractures has also been studied by ...

... this is in agreement with the results presented in chapter V

The inconsistent interpretations [redacted] the results in clinical measurements are probably one expla nation for the relatively large number of methods published in this field of orthopedic radio logy New methods for measurement [redacted] anteversion are successively proposed [redacted] order to com bine precision and simplicity

Chevrot (1976) has proposed two frontal projections of the hip with the x ray tube angulated in cranial and caudal direction along the femur which is kept in a constant position Computer programs of the trigonometric formula for this method have made it possible to choose the two angulations arbitrarily (Vanhoutte & Raeside 1978). Unfortunately, as expressed by the authors the results are often significantly poorer in clinical practice than in experiments One explana tion for this difference is that the computer program used does not correct for positional errors of the femur including the plane of reference at the knee The standard error (SD) of the com puterized method presented in this study is ± 3° when measuring anteversion relat...
long ideal axis of the fem...
[redacted] used The error ...

Angles on the films can be measured approximately with an accuracy of 0 5° – 1° When lines and axes are drawn to depict the angles on the films from bone further inaccuracy is added Quite different values of CD' can be achieved if the marking of the femoral shaft in the first projection is eccentric When CD' is large as in case 1 (table 14) an eccentric marking yields an anteversion AV that differs several degrees from the anteversion AV calculated from the true central axis A change of CD' in this case of 1° gives an error of about 0 5° in the anteversion AV

The results calculated here theoretically seem consistent with the experimental results obtained in bone models by Ruby et al with a standard error of 2 7° This standard error is of the same order in the computerized method (chapter I) However, an important difference between the methods is that the computerized one is independent of errors in orientation of the patient Such errors are inherent in the biplanar method and will therefore be discussed in the following.

Errors in orientation

Asymmetric positioning

In clinical practice inadequate position of the legs renders errors in the anteversion AV calculated (Gross & Haike 1970) As intended by the definition of the biplanar methods the femoral shafts must be symmetrically placed and parallel to the transverse plane in the second projection (fig 28) Otherwise, an error in AV' will arise This error is directly reflected with the same magnitude in the calculated anteversion AV The condition of parallelism implies that the angle (α) between the proximal shaft and the transverse plane is equal on both sides

When measuring torsion in femoral shaft fractures the conditions of parallelism can be difficult to fulfill if there is an apparent deformity of the fractured femur This difficulty can be avoided if the anteversion is defined relative to the short proximal axis of the femur, which constitutes one of the sides of the angle α (fig 28) The short axis was used when studying torsion with the computerized method (chapter V) When using the biplanar methods and measuring according to this definition the short axis should be parallel to the transverse plane, i e α = 0 on both sides

Inexact abduction

Gross & Haike (1970) discussed the errors of incorrect abduction in their experimental work However, they did not study the sensitivity to errors in abduction for different levels of anteversion The results in table 14 demonstrate that in high anteversion an error of the abduction (γ) of 1° gives an error of about 0 5° in the anteversion AV In clinical practice the error of (γ) is probably not less than 3° – 5°, perhaps larger, which means that the control of abduction is of importance

Determination of the plane of reference at the knee

The prerequisite in the use of the Rippstein or the Ryder–Crane methods is that there is no rotation of the femoral condyles when the position of the legs is shifted between the two exposures This assumption has not been tested in the methodological studies A possible rotation between the positions is a further source of error

This kind of error is eliminated when using the method described by Norman (1965) as well as the present method in which the femur is kept in a constant position As advocated by Norman (1969), all measurements of anteversion must be performed relative to a well defined plane of reference Such a well defined plane is the tangential plane to the dorsal parts of the femoral condyles and parallel to the long femoral axis The inclination of this tangential plane can be determined by fluoroscopy (Norman 1969) The computerized method in this study includes

determination of the inclination of the condyles by fluoroscopy According to the results in chapter I the plane of reference can be determined with an accuracy of about ± 0 5° – 1° Measurement relative to well-defined planes of reference at the knee has contributed to a better understanding of the variation of anteversion during childhood (chapter III)

The sources of error discussed, including the instability of the x ray apparatus, add to the final result given by the Gaussian formula for propagation of errors A standard error of at least 5° therefore seems reasonable when using a biplanar method clinically which is in accordance with the values found by Ruby et al

Interpretation of clinical measurements

The evaluation of a change in anteversion is usually based on a comparison with the contra lateral side assuming an original symmetry in normal individuals With a standard error of 5° the SD of differences in anteversion between normal right and left hips is $SD = \sqrt{5^2 + 5^2} \approx 7°$ and $2\ SD \approx 14°$ Such differences were found by Ruby et al when they measured normal hips with the biplanar method The largest difference was 16° No statistically significant asymmetry was found between normal right and left hips which is in accordance with our results (chapter III) In the follow up study of CDH (chapter IV) the possibilities of symmetrical or asymmetrical development of anteversion have been discussed

Torsion can be measured in femoral fractures, the torsion being defined as the difference in anteversion between the nonfractured and the fractured sides (chapter V)

Benum et al (1979) proposed that a difference of 5° in anteversion between the hips could indicate a torsion in the previously fractured femur The theoretical calculations and the experiments presented by Ruby et al demonstrate that a difference of 5° with the biplanar methods is too small to state that torsion exists

Torsion after previously traction treatment of femoral shaft fractures has also been studied by Piroth & Bliesener (1977) These authors also used the Rippstein method A difference of up to 10° was regarded as within normal Outward torsion of the distal fragment was the rule in their investigation This is in agreement with the results presented in chapter V

The inconsistent interpretations of the results in clinical measurements are probably one explanation for the relatively large number of methods published in this field of orthopedic radiology New methods for measurement of anteversion are successively proposed in order to combine precision and simplicity

Chevrot (1976) has proposed two frontal projections of the hip with the x ray tube angulated in cranial and caudal direction along the femur which is kept in a constant position Computer programs of the trigonometric formula for this method have made it possible to choose the two angulations arbitrarily (Vanhoutte & Raeside 1978) Unfortunately, as expressed by the authors, the results are often significantly poorer in clinical practice than in experiments One explanation for this difference is that the computer program used does not correct for positional errors of the femur including the plane of reference at the knee The standard error (SD) of the computerized method presented in this study is ± 3° when measuring anteversion relative to the long ideal axis of the femur (Billing 1954) and negligibly larger when the short proximal femur is used The error of method for the inclination is ± 2° It has been possible to reduce the error of method when determining angles radiographically by using the computer program (ANTEV) which in principle makes the determinations independent of the positioning of the patient.

Karl Friedrich Gauss

SUMMARY

The object of this investigation has been

to elaborate a method for accurate determination of anatomical angles from roentgenograms using a computerized technique and

to apply this method when measuring the anteversion and inclination of the femoral neck in children

First the limits of accuracy of measurement in this type of measurements, i e accuracy of measurement when determining angles from roentgenograms without any introduced indicator was investigated A theoretical analysis of the general principles for determination of angles from roentgenograms has been performed By the use of computer technique a practical method for determination of anatomical angles from roentgenograms has been evaluated and established No exactly defined position of the object to be measured is required In this study especially the anteversion and inclination of the femoral neck have been investigated, but the method is general and is directly applicable for determination of other anatomical angles in the body In the present investigation a Mimer III apparatus (Siemens Elema) was used, but the method can be performed with similar devices

In order to measure the angles of the hip, the child is placed on the table lying supine with the actual lower leg hanging freely over the edge of the table Three films are exposed

1 A frontal view of the hip
2 A lateral " " " "
3 A lateral view of the knee after translation of the x ray tube and the film

From the coordinates on the films of the anatomical landmarks and axes of the femur different defined angles can be calculated simultaneously The calculations have been performed using a minicomputer with the computer program ANTEV in FORTRAN

When measuring anteversion the accuracy is ± 3° (SD) and for inclination ± 2° (SD) The angles have been defined relative to the long ideal axis of the femur

All measurements of anteversion must be performed relative to a well defined plane of reference at the knee Two such planes have been studied

1 The frontal plane i e the horizontal plane in supine position.
2 The tangential plane to the dorsal parts of the femoral condyles parallel to the long axis of the femur

The inclination of the tangential plane to the femoral condyles has been determined by fluroscopy In fluoroscopy it is possible to determine the tangential plane to the femoral condyles with an accuracy of about ± 0 5° – 1°

The measurement of anteversion relative to a well defined plane of reference has contributed to a better understanding of the age-dependent change of anteversion during childhood

In young normal children there is a relative outward rotation of the femoral condyles of the neutrally rotated femur In adolescense this rotation is shifted to an inward rotation This means that the anteversion towards the frontal plane, i e the functional anteversion diminishes with growing age The anatomical anteversion, i e the angle of the femoral neck towards the tangent

Karl Friedrich Gauss

ACKNOWLEDGEMENTS

I am greatly indebted to Bo Jacobsson for his interest and constructive criticism throughout this investigation

I want to express my deep appreciation to Svend Erik Sörensen for keen support and encouragement in all stages of this work

Thanks are also due to Sven Scheller for valuable and much appreciated advice

The present investigation was performed in collaboration with colleagues from the Departments of Orthopaedic and Paediatric Surgery Harald Asplund, Göran Hansson, Bjorn Henrikson and Bertil Romanus

My old friend Tomas Blomberg wrote the computer program

Martin Riha introduced me to the computer

I had the privilege to discuss some special problems with Paul Edholm and Olof Norman.

Gudrun Hagberg and Anders Odén carried out the statistical calculations

Jan Bjure and Ingemar Claesson helped me in various ways

Inger Francke, Guri Anne Magnusson, Britta Sundstrom and Barbro Johansson typed the manuscripts

The illustrations were made by Inga Norling and the photographic work by Niels Roos.

To those mentioned above and to many others who made it possible to carry out this work I extend my sincere thanks

ial plane of the femoral condyles, does not diminish with age to such a degree as has been reported in previous studies

Only in girls does the anatomical anteversion, defined as the angle between the axis of the femoral neck and the tangential plane to the femoral condyles, diminish significantly during childhood

Another observation of biomechanical interest is the tendency to compensate for high anatomical anteversion at a given age with a relative inward rotation of the femoral condyles, and the opposite when the anteversion is low

A well defined group of children with congenital dislocation of the hips (CDH) treated with a von Rosen splint in the neonatal period was investigated at the age of 6 – 9 years The anteversion and inclination in the hips of these children as a group appeared to be within normal limits. These results are at variance with reports after Frejka treatment Follow up studies after such treatment have revealed remaining high anteversion in a number of children

Torsion in healed femoral shaft fractures in children treated with traction was also measured Outward torsion was the rule in the present series The maximum outward torsion did not exceed 30° A screening method has been proposed in order to judge if torsion is present or not If the inclinations of the femoral condyles in fluoroscopy are mainly symmetric further radiological investigations can be avoided as a torsion deformity is unlikely to be present in the fracture If the inclinations of the femoral condyles are asymmetric and differ more than 3°, a torsion may be present and further radiological investigation must be performed in order to determine the degree of torsion

In the closing general discussion the principal differences between conventional biplanar methods and the present computerized method were studied The sources of errors in biplanar methods type Rippstein, were analyzed theoretically A major restriction when using these methods is that the patient to be measured must be placed in a well defined position relative to the axes of projections These conditions are difficult to fulfill in clinical practice Such conditions are not required with the present computerized method which enables more precise determination of anatomical angles

ACKNOWLEDGEMENTS

An engineer who tries to perform specialist work in 'orthopedic biomechanics' often feels like a novice on skis – each leg on a separate support and both not necessarily moving in the same direction In such a position one often has to rely on help from others.

I gratefully acknowledge the help of all who contributed to the completion of this work

The research work was conducted under the supervision of Prof Dr Ir J D Janssen (Eindhoven University of Technology, Division of Applied Mechanics), Prof Dr T J J H Slooff and Prof Dr Th J G van Rens (University of Nijmegen, Department of Orthopaedics) I am very grateful for the opportunities they provided, their fruitful ideas, support and reviewing of the manuscript

My special thanks go out to the entire Department of Orthopaedics, University of Nijmegen, and to the members of the Division of Applied Mechanics, Department of Mechanical Engineering, Eindhoven University of Technology, for their positive attitude to my work and their invaluable support In this last group I must single out Ir Marcel Brekelmans and Dr Ir Frans Veldpaus who have so often advised me on matters of mechanics

To Ir Jos Banens (Computer Centre, Eindhoven University of Technology) who assisted me in the use of FEM computer systems, and to Ir Joost de Wijn (Laboratory of Dental Materials Research, University of Nijmegen), on whose expertise on biomaterials I have often relied, I wish to express my heartfelt thanks

Of great importance to the completion of the present work was the help of two engineering students, Jos van Heck and Ronald Schouten, who ran many computer programs for me, and medical student Frank Hoogbergen, who assisted me in reviewing the orthopedic literature

I am much indebted to Miss Marlies Lutkie, who typed the many draft manuscripts with unfailing accuracy, speed and above all, good humor Gratitude, too, I wish to express to Ir Ton de Lange for 'attending the shop' during the last months and for his help in the completion of the graphs.

I gratefully acknowledge the numerous useful suggestions of Mr A Smith Hardy in dealing with the vagaries of English

"To a scientist a mathematical model is as a stethoscope to a physician or a trowel to a bricklayer The model is an image of reality, an abstraction, which touches upon reality in such a manner as to render some if its characteristics visible It is the expedient relating complex systems to more trivial and simple systems, which last then represent the former The development of models enables us to compensate for the limits of our imagination and descriptive abilities, by refraining from details and concentrating on the essentials, the complex reality becomes surveyable, controllable and comprehensible"

CONTENTS

INTRODUCTION

Artificial joint replacement, the fixation of an artificial device to substitute for the kinematic and dynamic function of human joints, has become a widely accepted treatment in orthopedic surgery against advanced joint arthritis and disabling effects of post traumatic conditions and resective bone tumor surgery The performance of such a technical structure in the muscelo skeletal system is quite complicated and has many biological and mechanical aspects The long term survival of the fixation is not trivial and it is the aim of those concerned with these treatments to create the optimal conditions both from the biological and mechanical points of view

The need for better understanding of the complicated mechanical aspects of joints and joint replacements has given rise to collaboration between orthopedic surgeons and engineers in the fields of biomechanics and biomaterials In orthopedic biomechanics, a field fairly recently evolved, the mechanical functions and structure of normal bones, joints and connective tissues as well as the mechanical interaction between bones and artificial implants are studied The purpose of these investigations is to develop a better understanding, quantitatively, of the mechanical aspects of the muscelo skeletal system and provide criteria on the mechanical aspects of diagnostic methods and surgical interventions, for example artificial joint fixation The investigations described in the following chapters are the results of such interdisciplinary ventures carried out in the Laboratory for Experimental Orthopaedics at the Department of Orthopedics of the University of Nijmegen, where an 'Orthopedic Biomechanics' section was set up about 5 years ago, in collaboration with the Applied Mechanics Division of the Department of Mechanical Engineering at the Eindhoven University of Technology The studies were concerned with artificial joint loosening problems A more specific description of the objects of the studies will be given at the end of this introduction, where the contents and the sequence of the subjects presented will also be outlined

Since this area of activities is rather new to engineering disciplines, especially in the Netherlands, pains have been taken to sketch out a general outline of artificial joint replacement as an orthopedic treatment, its occurrence rate its problems and the contributions that engineers can possibly make, part of this will be discussed in the remainder of this introduction

Although not often recognized as such arthritis is one of the major disabling diseases in our society Some statistical data on arthritis in the U S A were cited by Chao (1976) in 1973 an Arthritis Foundation study showed that approximately 20 million Americans of whom more than 75% are between 45 and 65 years of age, have symptoms of arthritis In 1969, aged patients spent more than 70 million days in bed and employed people lost more than 14 million working days because of arthritis

Although not a cause of high mortality, arthritis inflicts severe pain and functional disability The economic consequences of this disease in terms of social security, manpower loss and health care are substantial

Since the development of artificial joints made its dramatic breakthrough in the early sixties, many patients with severe arthritis were successfully operated and now function normally and free from pain This development is illustrated in fig 1 (Gschwend, 1976) giving the number of artificial hip replacements and other treatments of arthritis as carried out in Swiss clinics

Although the success of artificial joint replacement dates back relatively few years, the development started a long time ago Excellent reviews of the history in this respect have been given by Walker (1977) and Huggler and Schreiber (1978)

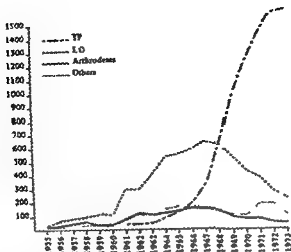

fig 1 Number of hip operations for osteoarthritis in 9 Swiss orthopedic clinics, 1955 1973. TP total hip replacement, IO intertrochanteric osteotomy (where anatomical proportions of the joint are changed), arthrodeses: Suffening of the joint (reproduced with permission of Gschwend, 1976).

Due to the important kinematic and load-bearing function of the hip and the high number of patients suffering from degenerative hip diseases, the first and main efforts in artificial joint replacement were focussed on this joint

Starting early this century, many methods of treatment and materials were tried. More-or-less successful trials have been reported by Smith Petersen (1939), Moore and Bohlman (1943) and Judet (1954) among others In their different replacement concepts, only one bone component of the joint was replaced in function with the normal cartilage of the other component Wiles (1957) reported on operations on patients using a total hip replacement, where both sides of the joint were replaced, by a femoral and an acetabular component respectively

Although surgical procedures in general became more successful in the course of this century, thanks to better antiseptic measures and anesthetic procedures, the short and long term results of the early joint replacement trials were relatively speaking rather poor, mainly because of the lack of an adequate fixation These circumstances changed after Charnley (1960) introduced the use of acrylic cement as space filling fixation material and his concept of 'low-friction' total hip arthroplasty, replacing the acetabular component of the joint with a plastic cup and the femoral component with a metal endoprosthesis

Acrylic cement, or bone cement, is a 'cold-curing' plastic. It consists of a mixture of polymethylmethacrylate and monomethylmethacrylate and is inserted in the bone in a doughy phase, allowing the surgeon to mold it between the implant and the bone After a few minutes it polymerizes to a solid substance Although the acrylic cement sticks neither to the bone, nor to the implant, the space filling capacities guarantee a smoothening of the load distribution and a firm placing of the implant. Fig 2 shows a schematic illustration of a cemented Charnley hip prosthesis

The results reported by Charnley (1972) were extraordinarily good and following this breakthrough total hip replacements have been carried out in ever growing numbers, making it one of the major surgical interventions in orthopedic clinics today

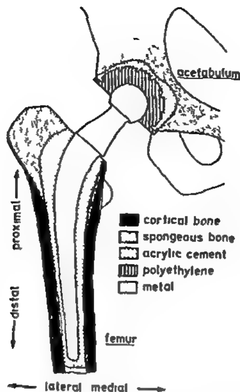

fig 2 Schematic illustration of a Charnley total hip prosthesis (acetabular and femoral component) fixated in the bone with acrylic cement Distal and proximal, medial and lateral directions are indicated

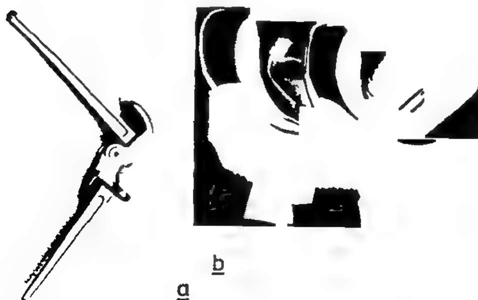

fig 3 Artificial knee joints are available in two principally different concepts, hinged and surface types Examples are (a) G U E P A R (hinged type) and (b) Geomedic (surface type)
(Reproduced with permission of v Rens and Huiskes, 1976)

Although the hip joint still receives the most attention, developments have rapidly expanded to other joints Artificial hinges for the knee joint were already developed by Moeys (1954), Shiers (1954) and Walldius (1957), followed by numerous designs for knee surface replacement and other hinged joints in the nineteen seventies (fig. 3) Attention was given as early as the nineteen fifties to the elbow, the shoulder and the finger joints, recently followed by the ankle and wrist Several designs are now available for various joints and especially the hip and the knee are being replaced routinely in most orthopedic clinics
In the Orthopedic Department of the University of Nijmegen in 1977 artificial joint replacement was carried out in roughly 20% of all operative interventions and it accounted for approximately 30% of the total operation time, 75% of the replacements were in the hip and 23% in the knee joint
Using estimates from several sources, an assessment was made of the number of total joint replacements carried out annually in the U S A by Hori *et al* (1978) In their questionnaire they not only investigated the number of replacements carried out, but also included the number of patients that were indicated for an artificial joint but did not receive one because, in the opinion of the surgeon no reliable design was available A summary of their results is given in table I

	1972	1973	1974	1975	1976	Total	1976
	implanted						indicated
Hip	55,000	75 000	77,500	80,000	80,000	367,500	89,600
Knee	4,000	10,000	20,000	32,500	40,000	106,500	52,800
Others	2,500	3 800	6 500	8,500	10,000	31,300	33,900
Total	61 500	88 800	104 000	121,000	130,000	505,300	176,300

table I *Estimated number of joint replacements carried out annually in the U S A from 1972 to 1976 and indicated number of joint replacements in 1976 (after Hori et al, 1978)*

Data with respect to the number of joint replacements carried out in the Netherlands were supplied by the Foundation for Medical Registration (table II)

Hip	7,277	Hand (wrist included)	uncertain
Knee	643	Shoulder	29
Elbow	30	Ankle	no data

table II *Number of arthroplasties (non-artificial included) carried out in 1977 in the Netherlands (source Found Med Registration, Utrecht, the Netherlands)*

It can be estimated that in the near future somewhere around 300,000 artificial joint replacements will be performed annually in the world If we assume an average life expectancy of the patients to be approximately 8 years (an arbitrary estimate), we find that on the average soms [redacted] 4 million people with artificial joints will be alive

Although widely applied, artificial joint replacement is not without complications Some of these are characteristic of all major operations, others are more specific The most troublesome of these specific complications is loosening of the device, directly or indirectly caused by a variety of mechanical and biological phenomena In patient reviews it was established that the incidence of loosening rises steeply with the amount of postoperative years This has resulted in many revision and salvage operations Moreover, generally speaking, it limits the application of artificial joints to older people, the present criterion being about 55 years and over Still, the need for joint replacement in young patients is anything but negligible Presently, many efforts by scientists from medical and engineering disciplines are being put into the development of artificial joints and fixation procedures that will diminish the complications and guarantee longer service life

The function of an artificial joint is purely mechanical, although of course the biological reactions of the bone and the soft tissues play important and complicating roles The joint has to provide for a kinematic system that accords with the kinematic characteristics of the original joint, it has to be able to stand up to the physiological joint loading and experience little wear and friction, the material should not induce undesirable tissue reactions and has to transfer the load to the bone in such a way that a rigid fixation remains intact for many years

Until very recently artificial joints were being developed more or less by 'trial and error' After a certain number of patients had received a specific design and a number of postoperative years had passed, the patients were reviewed Based on the short and long term findings, the design was often adapted or dropped altogether Only seldom could a causative relation be established between the failures and the characteristics of the design A good design may have been rejected merely because it was inadequately implanted and a bad design may have been widely accepted only because the surgeon designer carried out the first operations exceptionally well, quite individual accomplishments perhaps not reproducable by others Also, quite good designs may have been rejected as a whole in the past, only because minor and easily changeable details had led to complications As a result of this development, many types of prostheses are presently available for the different joints These different types can be divided into a small number of categories, within each category the differences are only those of detail If we count only the popular' types, about 48 different designs of knee prostheses are available, 10 different elbow prostheses, 4 different shoulder prostheses, 6 different ankle prostheses, around 10 different finger prostheses, a few wrist prostheses and the different designs of hip prostheses available far exceed a hundred New designs, sometimes differing only slightly, are developed yearly Few objective criteria are known for a justified choice between the different makes and, if a choice is made, the orthopedic surgeon usually never finds out whether failures are due to an inadequate surgical procedure, to individual properties of the patient or to the design features

It is the object of the research work described in the following chapters to provide a more fundamental comprehension of some aspects of artificial joints and their performance in the body Two subjects of investigation have been chosen both regarding the incidence of implant loosening First the cause of bone necrosis as usually seen directly after the operation in a small zone close to the acrylic cement adjoining the bone, and more specifically, the possible effect in this phenomenon of the heat developed in the acrylic cement during the polymerization process This part of the work is described in section II Second the stress distribution in the implant the acrylic cement the bone and on the contact regions [illegible] to the strength of [illegible] onfined to intra [illegible] cavity of the medullary fixation systems, prostheses that are fixated [illegible]

bones, using a stem, and although the methods that will be discussed and some of the results are valid for these systems in general, the analyses are principally focussed on the hip endoprosthesis This part of the work is treated in section III

Although results of experiments carried out in our own laboratories as well as those published in the literature will be used, the approach in both areas is mainly analytical Principles of mechanics and heat conduction theory will be applied to evaluate the system behavior and the influences of the system parameters This approach is not quite common in orthopedics and it is felt that, especially in this respect the (biomechanical) engineer can make a contribution to better fundamental understanding of the bone implant structure and some of its problems

It should be understood that such a contribution to a more fundamental understanding of some phenomena was the object of the work presented and that no new device or material is envisaged, although some objective quantitative guidelines for prosthesis designs and surgical procedures will result and moreover, a simple method will be proposed that can be used to predict the mechanical performance of specific endoprosthesis designs in patients and hence clear the way to a more 'custom fit' approach

The two investigations described here are not the first ventures into the problem areas, nor will they be the last, part of the work has been devoted to an evaluation of studies published in the literature, a review of which is presented also in sections II and III, respectively As the approach is uncommon in orthopedics and the methods used are of a quite complicated nature from a medical point of view, the possibilities and limitations of theoretical methods are discussed to a somewhat greater extent in section I and some relevant conclusions will be discussed in more general terms in section IV

Section I also gives a more detailed characterization of artificial joints and artificial joint replacement and describes some properties of the bone implant system as far as they are relevant to the analyses presented Complications of artificial joint replacement, especially prosthesis loosening, will be discussed based on a review of the literature on this subject in section I too, after which the objects of the investigations presented in sections II and III will be defined in more detail

INTRODUCTION

In this section some general aspects of artificial-joint replacement are described as far as deemed relevant to an understanding of the objects and results of the studies discussed in sections II and III. Workers in medical as well as technical fields may encounter trivial information, because this section is meant to be an introduction for both Properties of the bone prosthesis system, relevant for the analyses, are described in chapter 1
In chapter 2 a short review is given of literature data on complications of artificial joint replacement, especially concerning prosthesis loosening The objects and methods of the present studies are outlined in chapter 3.
Although some general aspects of artificial joint replacement are discussed in this section, most are focussed on the hip joint

CHAPTER ONE

CHARACTERIZATION AND PROPERTIES OF BONE-IMPLANT SYSTEMS

1 1 Surgical procedure

A division can be made into intramedullary fixated implants (endoprostheses), where a prosthesis stem is fixed into the meduallary cavity, and surface replacement, where the implant is more or less fixated against the bone Some prostheses for instance tibial components of some knee prostheses, use a mixed form of fixation
In both cases parts of the bones involved in the articulation are resected When an intramedullary stem is used, the medullar cavity is cleaned and reamed to some extent In this procedure a part of the vascularity system that nourishes the bone is, at least temporarily, disturbed, especially in the diaphyseal region Presently, most of the artificial joints are *fixated by means of acrylic cement The two components of this cement are mixed by the* surgeon during the operation The curing process starts right after the mixing procedure and takes something in the order of 5 10 minutes Still in a doughy state, the cement is inserted into the medullar cavity or positioned against the bone, the prosthesis is then pressed into the cement mass and held until the cement has cured to a solid mass
Especially with intramedullary fixated implants the surgeon has no complete control over the consistency and the thickness of the cement mantle Often air, bone debris and blood are mixed in the cement and the distal part of the cement mass may be pushed downward into the medullar canal
It has been recognized that a syringe should be used, to ensure a complete and homogeneous cement mantle (Slooff, 1969)
Recently the use of an intramedullary bone plug has been advocated to enable more pressure to be put on the cement mass during insertion and prevent the distal cement mass from

CHAPTER ONE

CHARACTERIZATION AND PROPERTIES OF BONE-IMPLANT SYSTEMS

1 1 Surgical procedure

A division can be made into intramedullary fixated implants (endoprostheses), where a prosthesis stem is fixed into the meduallary cavity and surface replacement, where the implant is more or less fixated against the bone Some prostheses, for instance tibial components of some knee prostheses, use a mixed form of fixation.
In both cases parts of the bones involved in the articulation are resected When an intramedullary stem is used the medullar cavity is cleaned and reamed to some extent. In this procedure a part of the vascularity system that nourishes the bone is at least temporarily disturbed especially in the diaphyseal region Presently, most of the artificial joints are fixated by means of acrylic cement. The two components of this cement are mixed by the surgeon during the operation The curing process starts right after the mixing procedure and takes something in the order of 5 10 minutes Still in a doughy state, the cement is inserted into the medullar cavity or positioned against the bone, the prosthesis is then pressed into the cement mass and held until the cement has cured to a solid mass
Especially with intramedullary fixated implants the surgeon has no complete control over the consistency and the thickness of the cement mantle Often air, bone debris and blood are mixed in the cement and the distal part of the cement mass may be pushed downward into the medullar canal
It has been recognized that a syringe should be used, to ensure a complete and homogeneous cement mantle (Slooff 1969)
Recently the use of an intramedullary bone plug has been advocated to enable more pressure to be put on the cement mass during insertion and prevent the distal cement mass from

being pushed downward (Markolf and Amstutz, 1976, Oh *et al*, 1978, Krause *et al*, 1979, Weber and Stuhmer, 1979) Pulsatile water lavage before cement insertion has been advised in order to clean the bony implant bed prior to fixation of all prostheses (Narten *et al*, 1977, Halawa *et al*, 1978, Miller *et al*, 1978)
A very important part of the operation is the positioning and alignment of the prosthesis Usually this is done by visual judgement
Some complications, called preoperative complications, may occur during the operation, these include perforation of the implant through the bone, fracture of the bone, injury to arteries or veins, injury to nerves, anesthetic complications, embolies and several others

1 2 Basic requirements for artificial joints

An artificial joint has to approximate as closely as possible the natural joint function for the full postoperative life span, without discomfort and complications More specifically some practical requirements can be formulated that have to be taken into account when new designs or surgical procedures are being considered

- The prosthesis and fixation materials should not induce undesirable tissue reactions, as bone necrosis or bone resorption, they should have acceptable friction and wear characteristics and not corrode
- The surgical procedure should be relatively simple and fast, standardized and repro duceable, with minimal surgical trauma
- The design of the prosthesis, the choice of materials, with reference to strength as well as stiffness properties should be such as to guarantee adequate mechanical performance in such a way that stress concentrations are avoided and that implant, cement, bone and the relevant interfaces are not loaded beyond their strength or fatique limits
- The implant should have a good salvage potential, meaning that if the system fails, another solution remains possible Since the ultimate salvage solution is usually arthro deses for instance this means that as little bone as possible should have to be resected
- Early mobilization sterilization of the components and reasonable manufacturing costs of the implant should all be possible

Obviously an adequate artificial joint design will always be a trade off between these different requirements A mechanical compromise that usually has to be considered is the one between requirements of range of motion and degrees of freedom (or constraints) on th one hand and of stability on the other A low constraint joint that has an extensive range of motion in other words is free to move in several directions in an extensive range, will o the one hand offer little stability, but on the other hand will have to transfer less loading the fixation system, hence will give less rise to mechanical loosening than a highly con... ed joint with a limited range of motion

1 3 Implant shapes and materials

Artificial joints are available in a variety of types and shapes Intramedullary stems are used in different designs for all joints but the ankle The acetabular part of the hip prosthesis is surface replacement, the femoral part usually has an intramedullary stem although since recently surface replacement of the femoral head is also becoming popular (double cup prosthesis) The hinged knee prostheses are usually intramedullary fixated, some of the kn

ırface replacements also have intramedullary stems Finger prostheses, elbow prostheses ıd shoulder prostheses use intramedullary fixation in all cases The artificial wrist joint is sually a surface replacement combined with a stem for both components

'he configuration of the artificial joint greatly depends on the kinematic function it has to ıerform and the stability it has to give Three basic configurations are (e g Chao, 1976) he ball and-socket design (hip, shoulder), the articulating-type with various degrees of reedom (knee, ankle, elbow, wrist), the hinged types (knee, finger, elbow) Combinations ıf these basic types are also used.
The designs may also vary greatly in shape and dimensions, even if functionally identical A dimensional classification of about 20 popular hip joint designs was given by Walker 1977) diameters of the prosthesis femoral head vary from 22 to 48 mm, neck lengths vary from 15 to 55 mm, stem lengths from 93 to 180 mm and a few exceptional stems from 240 to 370 mm The stem may be strongly curved or rather straight, while different kinds of cross-sectional geometries are used (diamond-shaped, rectangular, rounded-off, triangular, oval) Some designs use a more or less pronounced collar on the proximal side of the stem, resting on the bone rim The stem is usually tapered to a greater or lesser extent

Many different implant materials have been used in the past They must be strong, tough, resistent to fatigue and wear, tolerated by the body and processable at reasonable costs Because of the favorable friction and wear properties, most designs presently use a metal component against a plastic component The metal components usually consist of high grade stainless steel, cobalt chromium alloys or titanium alloys, the plastic components of high density polyethylene (HDPE) or ultra high molecular weight polyethylene (UHMWP) Experiments are being carried out with ceramics, Delrin and composite materials Silastic is being used in finger prostheses The femoral part of the total hip replacement is always fabricated in metal and the acetabular cup usually in plastic An extensive review of materials used for human implantation and their properties has been published by Rostoker and Galante (1979)

1 4 Loading of the joint

By the joint loading is meant the resulting force and moment that one joint component exerts on the other and vice versa, by means of their articulating contacts
The kind of loading depends on the kind and intensity of the activity The loading is caused by gravity forces acceleration forces muscle forces and forces due to ligament constraints Investigations of human joint loading belong to the first activities in biomechanics and date back many ages Many studies on this subject have been published and many are still being carried out A review of the relevant literature is given by Walker (1977) Since the joint forces cannot be measured directly they have to be estimated using equilibrium conditions and data from force plate studies (measuring the ground reaction force), EMG studies (electromyography giving an indication at large of muscle activity), movement studies and anthropometric measurements Promising new possibilities are those of computer simulation, modeling the complete skeletal system as a kinematic chain, taking the important muscle groups into account and solving the redundant problem using optimization criteria. A first effort in this direction was published by Seireg and Arvikar (1975)
Although reliable data, accurate in an absolute sense, is not available as yet, results of various studies indicate that the joint forces are much higher than sometimes assumed Brewster *et al* (1974) have calculated from force plate studies that the force in the ankle joint

being pushed downward (Markolf and Amstutz, 1976, Oh *et al*, 1978, Krause *et al*, 1979, Weber and Stuhmer, 1979) Pulsatile water lavage before cement insertion has been advised in order to clean the bony implant bed prior to fixation of all prostheses (Narten *et al*, 1977, Halawa *et al*, 1978, Miller *et al*, 1978)

A very important part of the operation is the positioning and alignment of the prosthesis Usually this is done by visual judgement

Some complications, called preoperative complications, may occur during the operation, these include perforation of the implant through the bone, fracture of the bone, injury to arteries or veins, injury to nerves, anesthetic complications, embolies and several others

1 2 Basic requirements for artificial joints

An artificial joint has to approximate as closely as possible the natural joint function for the full postoperative life span, without discomfort and complications More specifically some practical requirements can be formulated that have to be taken into account when new designs or surgical procedures are being considered

- The prosthesis and fixation materials should not induce undesirable tissue reactions, as bone necrosis or bone resorption, they should have acceptable friction and wear characteristics and not corrode
- The surgical procedure should be relatively simple and fast, standardized and reproduceable, with minimal surgical trauma
- The design of the prosthesis, the choice of materials, with reference to strength as well as stiffness properties, should be such as to guarantee adequate mechanical performance in such a way that stress concentrations are avoided and that implant, cement, bone and the relevant interfaces are not loaded beyond their strength or fatique limits
- The implant should have a good salvage potential, meaning that if the system fails, another solution remains possible Since the ultimate salvage solution is usually arthrodeses, for instance this means that as little bone as possible should have to be resected
- Early mobilization, sterilization of the components and reasonable manufacturing costs of the implant should all be possible

Obviously an adequate artificial joint design will always be a trade off between these different requirements A mechanical compromise that usually has to be considered is the one between requirements of range of motion and degrees of freedom (or constraints) on th one hand, and of stability on the other A low constraint joint that has an extensive range of motion in other words, is free to move in several directions in an extensive range, will o the one hand offer little stability, but on the other hand will have to transfer less loading to the fixation system, hence will give less rise to mechanical loosening than a highly constrai ed joint with a limited range of motion

1 3 Implant shapes and materials

polymerizing spontaneously, and also an initiator (benzoyl peroxide) To the power component an accelerator is added (dimethyl paratoluidine, DPT) After mixture of the components the initiator is decomposed by the accelerator into so called radicals, molecule that trigger off the polymerization of the monomer The compositions of the various commercial brands vary to some extent The characteristics of the polymerization process are usually defined with reference to the temperature time curve (fig 1 3) the time from starting the mixture

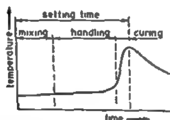

fig 1 3 A typical temperature time curve of curing acrylic cement Terminology for phases in the polymerization process is shown (see also text)

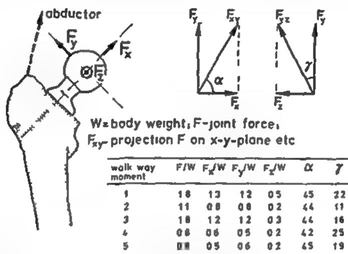

until the peak temperature occurs is called the 'setting time', which is roughly 10 minutes, the first stage of this period, that takes about 3 to 4 minutes and in which the mixture tends to 'stick to the surgical glove', is called the 'mixing time' or 'dough time', the second stage, that takes about 4 5 minutes and in which the mixture is still dough but no longer sticks to the glove, is called the handling time' There appears to be no complete agreement on this terminology in the literature and, moreover, these stages are not uniquely defined, because the temperature time curve depends not only on the cement ... heat

... polymerization process were carried out by Debrunner *et al* (1976), an example of results is shown in fig 1 4

during normal walking can be as high as 4 5 to 5 5 times body weight Forces in the kne joint would reach about 3 times body weight and in the hip joint about 4 times body w during normal walking, according to Paul (1974) During stairs walking or sport activiti these values will be even higher

The loading on the artificial joint is not necessarily equal to the loading on the natural j Even if the same level of activity were assumed, differences may be due to the positioni of the joint relative to the bone, the constraints offered by the prosthesis in comparison those of the natural joint, and the incidence of friction

Valuable data on hip joint loading was supplied by Rydell (1966) who implanted endo prostheses instrumented with strain gauges in two patients and measured the hip joint fo in several activities An example of his results is shown in fig 1 1 Magnitude and directi

walk way moment	F/W	F_x/W	F_y/W	F_z/W	α	γ
1	1 8	1 3	1 2	0 5	45	22
2	1 1	0 8	0 8	0 2	44	11
3	1 8	1 2	1 2	0 3	44	16
4	0 8	0 6	0 5	0 2	42	25
5	[illegible]	0 5	0 6	0 2	45	19

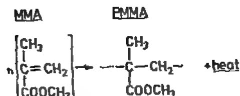

fig 1 1 Magnitudes, directions and points of application of hip joint forces as measured Rydell (1966), using an instrumented hip prosthesis implanted in a 51 yr old ma patient (right leg, weight 75 kg), during level walking at 1 3 m/sec Averages out of 12 measurements Also shown is the resultant force of the important abducto muscle group on which magnitude and direction the joint force partly depends

of the resultant joint forces varied considerably during the different activities and in the two patients The maximal average force amounted to roughly 4 3 times body weight ($\alpha \approx 32°$ and $\gamma \approx 15°$) during running at 2 5 m/sec and was measured in patient no 2 (56 yrs, female, 45 kg)

The loading that is transferred by the fixation system ultimately determines the stress distri bution This loading, in addition to the joint loading depends on the geometry of the implant In the case of the hip joint, the neck length and the varus valgus angle of the neck are important parameters Other forces, too will influence the stress distribution in the bone prosthesis structure as for instance the abductor muscle forces (fig 1 1)

1 5 Acrylic cement

Acrylic cement is a two component material The solid powder component consists princi pally of polymethylmethacrylate (PMMA) or polymer, the liquid component principally of monomethylmethacrylate (MMA) or monomer Shortly after mixture of the two componen

$$n\left[\begin{array}{l}CH_3\\ |\\ C=CH_2\\ |\\ COOCH_3\end{array}\right] \rightarrow \text{—}\begin{array}{c}CH_3\\ |\\ C\\ |\\ COOCH_3\end{array}\text{—}CH_2\text{—} \quad +\text{heat}$$

fig 1.2 Description of the polymerization reaction in which monomethylmethacrylate molecules are connected to form polymer chains

the polymerization process of the monomer starts (fig 1 2), ultimately embedding the PMMA powder into a PMMA matrix, so that a solid substance remains During the polymerization process heat is generated which has to be conducted through the adjoining materials, implant and bone The total amount of generated heat is directly proportional to the mass of monomer used (Trommsdorf, 1963)

In more detail, the polymerization process of acrylic cement can be described as follows (Charnley, 1970, de Wijn, 1974, Oest *et al*, 1975, Debrunner *et al*, 1976) to the liquid component are added an inhibitor or stabilizer (hydroquinon) that prevents the monomer from polymerizing spontaneously, and also an initiator (benzoyl peroxide) To the power component an accelerator is added (dimethyl paratoluidine, DPT) After mixture of the components the initiator is decomposed by the accelerator into so called radicals, molecule that trigger off the polymerization of the monomer The compositions of the various commercial brands vary to some extent The characteristics of the polymerization process are usually defined with reference to the temperature time curve (fig 1 3) the time from starting the mixture

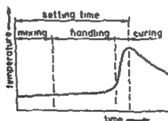

fig 1 3 A typical temperature time curve of curing acrylic cement Terminology for phases in the polymerization process is shown (see also text)

until the peak temperature occurs is called the setting time' which is roughly 10 m... the f... to ... ds tha ... xture is still dough but no longer sticks to the glove, is called the 'handling time' There appears to be no complete agreement on this terminology in the literature and moreover, these stages are not uniquely defined, because the temperature time curve depends not only on the cement properties, but also on the heat conduction properties of the adjoining materials, hence on the specific circumstances The mixture reaches its ultimate hardness (sets) somewhat prior to the occurrence of the peak temperature Hardness tests during the polymerization process were carried out by Debrunner *et al* (1976), an example of results is shown in fig 1 4

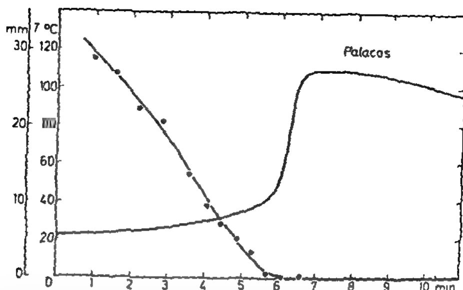

fig 1 4 Temperature and hardness of curing acrylic cement, as function of time Hardness was measured as penetration depth (mm) at constant force (reproduced with permission of Debrunner et al, 1976)

During the polymerization process the mixture undergoes dimensional changes due to volume contraction of the polymerizing component (density of PMMA 1 18 kg/m^3, density of MMA 0 94 kg/m^3), expansion of enclosed air and vaporized monomer bubbles and thermal shrinkage The first two mechanisms are active during the setting phase, while the last named occurs during the cooling phase An overall expansion of 2 to 5 volume percent has been mentioned in the literature (de Wijn *et al*, 1975) These authors concluded that in fixating intramedullary stems the initial expansion will propably cause the mixture to flow in a longitudinal direction, while the cooling will cause the layer to shrink around the stem, leaving a gap between the bone and the cement mass (at the so called 'cement bone interface') and locked in stresses in the cement layer Sometimes these stresses will cause the cement mantle to fracture during the operation (Miller *et al*, 1976, Chao, 1979)
The steep rise in temperature after the mixture has set is related to an acceleration of the polymerization process, called the 'Trommsdorf' or 'gel' effect
The initial velocity of the polymerization process depends very much on the initial temperature, owing to the temperature sensitivity of the catalyser The polymerization is never complete It has been shown that there is 2 to 5% residual monomer in the cement and that 1 to 2% gradually enters into the tissue (e g Kutzner *et al*, 1974) This residual monomer may cause damage to the bone tissue adjoining the cement (e g Mohr, 1958)
Apart from the ones already mentioned, other components may have been added to the cement, like antibiotics or radiopaque fillers (barium sulfate, $BaSO_4$ or zirconium oxide, ZrO_2)

The mechanical properties of acrylic cement (e g strength and stiffness) as present in the patient are different from those of industrial PMMA Differences are due to inhomogeneties [illegible]

[illegible] rature influences, moisture uptake and ageing Extensive studies on mechanical properties of bone cement, preoperative as well as postoperative, have been published by Muller (1975,

Conditions	Young's modulus (N/mm^2)	Ultimate tensile strength (N/mm^2)	Elongation at fracture (%)
industrial PMMA,	2 8 x 10^3	74	8 4
acrylic cement, laboratory conditions,	2 6 x 10^3	43	2 0
10 months in the body simulated, tested at 37°C	1 9 x 10^3	23	1 7

table 1 I Approximative average value of five commercial brands for mechanical properties of acrylic cement, tested under different conditions, compared to properties of industrial PMMA (after Kusy, 1978)

1979), Lee et *al* (1978) and Kusy (1978) Kusy reports mechanical properties for five brands tested under different conditions (table 1 I) The acrylic cement is many times stronger in compression than in tension Lautenschlager et *al* (1974) report 20 7 to 34 5 N/mm^2 ultimate compressive strength and 6 9 to 20 7 N/mm^2 ultimate tensile strength It should be remarked that bone cement is somewhat viscoelastic, hence differences in strain rate may, apart from other circumstances, explain the variety in results to some extent. Lee *et al* (1978) investigated influences of several variables that may weaken the bone cement, a summary of their results is shown in table 1 II

Variable	Possible % change in strength		
	UCS		UTS
Environmental temp 37°C		- 10%	
Equilibrium moisture content		- 3%	
Ageing		- 10%	
Radiopaque fillers		- 5%	
Antibiotics		- 4%	
Inferior mixing technique		- 21%	
Insertion technique – delay	- 40%		- 54%
– pressure		+ 20%	
Inclusion of blood and tissue debris	- 16%		- 70%

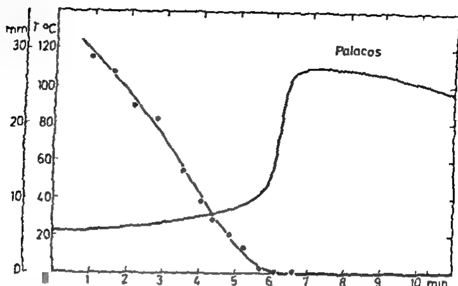

fig 1 4 Temperature and hardness of curing acrylic cement, as function of time Hardness was measured as penetration depth (mm) at constant force (reproduced with permission of Debrunner et al, 1976)

During the polymerization process the mixture undergoes dimensional changes due to volume contraction of the polymerizing component (density of PMMA 1 18 kg/m^3, density of MMA 0 94 kg/m^3), expansion of enclosed air and vaporized monomer bubbles and thermal shrinkage The first two mechanisms are active during the setting phase, while the last named occurs during the cooling phase An overall expansion of 2 to 5 volume percent has been mentioned in the literature (de Wijn *et al*, 1975) These authors concluded that in fixating intramedullary stems the initial expansion will propably cause the mixture to flow in a longitudinal direction, while the cooling will cause the layer to shrink around the stem, leaving a gap between the bone and the cement mass (at the so called 'cement bone interface' and locked in stresses in the cement layer Sometimes these stresses will cause the cement mantle to fracture during the operation (Miller *et al*, 1976, Chao, 1979)
The steep rise in temperature after the mixture has set is related to an acceleration of the polymerization process, called the 'Trommsdorf' or 'gel' effect
The initial velocity of the polymerization process depends very much on the initial temperature, owing to the temperature sensitivity of the catalyser The polymerization is never complete It has been shown that there is 2 to 5% residual monomer in the cement and that 1 to 2% gradually enters into the tissue (e g Kutzner *et al*, 1974) This residual monomer may cause damage to the bone tissue adjoining the cement (e g Mohr, 1958)
Apart from the ones already mentioned, other components may have been added to the cement, like antibiotics or radiopaque fillers (barium sulfate, $BaSO_4$ or zirconium oxide, ZrO_2)

The mechanical properties of acrylic cement (e g strength and stiffness) as present in the [illegible] d fferent from those of industrial PMMA Differences are due to inhomogeneties [illegible]

the polymerization process The properties also change [illegible] rature influences, moisture uptake and ageing Extensive studies on mechanical properties of bone cement, preoperative as well as postoperative, have been published by Müller (1975

ig 1 6 shows an example of this phenomenon

fig 1 6 Roentgen series showing calcar and acetabular (medial side of the cup) bone resorption (indicated by arrows) after total hip replacement, respectively directly (a), 2 months (b) 3 years (c) and 6 5 years (d) postoperative (patient material Department of Orthopedics University of Nijmegen, the Netherlands)

Many investigations (cited in section III) have shown that the orientation and density distribution of trabecular and cortical bone coincide with optimal structural requirements to resist the stresses due to the loading of the bone From these observations Wolff s law has been formulated (Koch 1917) stating that bone growth is related to the stress (or strain[1]) pattern in the bone It would according to this law not be illogical if at least part of the remodeling phenomena were caused by the effect of the greatly changed stress pattern in the bone after the joint has been replaced Especially disuse osteoporosis as the name indicates is attributed to this stress effect

The process of calcar resorption is not yet fully understood Its occurrence has been attributed to effects of vascular damage (e g Rhinelander, 1972, 1979) while some investigators support the opinion that it is initiated by foreign body reactions to wear particles (e g Willert *et al* 1976 1978)
Another hypothesis often put forward is that of a stress related effect Especially in the calcar region the stress pattern is greatly changed after joint replacement Upon joint loading unphysiological radial and shear stress components will be present at the inner surface of the bone (fig 1 7) and an unphysiological circumferent al [illegible]
the bone cortex The axial normal stress in the
if a collar is applied on the prosthesis but will
(fig 1 7) Hence resorption might occur due to overloading, but also to underloading

materials, allowing bone to grow in, as for instance porous acrylic cements (Feith, 1975, de Wijn *et al*, 1977, 1978, Ypma *et al*, 1978) and porous implant coatings (e g Ducheyne *et al*, 1977, Spector *et al*, 1978)

1 6 Bone reaction to joint replacement

Bone tissue can be divided into sponge like trabecular bone and dense cortical bone Trabecular or spongeous bone is for instance found in the proximal and distal parts of the long bones, near the joints (fig 1 5 a) Hence the greater part of the bone to be resected for joint replacement will be spongeous bone (fig 1 5 b)

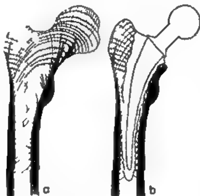

fig 1 5 A schematic representation of bone structure, showing trabecular bone and cortical bone in the upper femur, before (a) and after (b) hip joint replacement (reproduced with permission of Willert and Semlitsch, 1976)

Bone is a living material and is constantly being resorbed and appositioned a process called bone remodeling Due to this process the conditions in the biological part of the bone prosthesis system gradually alter to a greater or lesser extent after the operation Initially the bone remodeling process is usually restorative with respect to the surgical trauma At a later stage progressive resorption caused by biochemical or mechanical factors may seriously endanger the service life span of the system

A bone reaction that is of great importance for the functioning of the bone prosthesis system is that of the bony implant bed, during and directly after the operation, but also at a later stage The behavior of this bone cement interface' will be discussed in paragraph 1 7 After intramedullary joint fixation, reactions occur that are typical for all intramedullary procedures An extensive literature review with respect to these reactions is given by Feith (1975) The reactions, that are usually attributed to a disturbance of the intramedullar vascularity that nourishes the cortex, include necrosis of the inner part of the cortex, the appearance of large resorption lacunae in the middle third of the cortex (spongiozation of the cortex, Slooff, 1970) and subperiosteal bone apposition
Another reaction often encountered is a phenomenon called disuse osteoporosis , a process that may gradually occur postoperatively and in which the cortical bone becomes porous, thus affecting its mechanical properties such as strength and stiffness A last significant reaction specific to hip joint replacement is called 'calcar resorption , a process in which the bone rim in the calcar region resorbs to a greater or lesser extent (e g Charnley, 1978)

adequate performance of the bone prosthesis system However, due to the biological character of the bone, the structure of the interface will change postoperatively, both immediately and in the course of time Histological studies on the short and long term reaction of the bony implant bed were for example published by Charnley (1970 1978), Willert *et al* (1972, 1974, 1976, 1978) and Vernon Roberts and Freeman (1976, 1977)
In the first instance directly postoperatively a layer of necrotic bone of a few mm thick ness is usually found at the interface Three factors may contribute so this phenomenon
- the reaming of the implant bed and the disturbed vascularity,
- the thermal effects of the heat of polymerizing of the acrylic cement
- the cytotoxic effect of the residual monomer

Vernon Roberts and Freeman (1976 1977) believe that the first effect is the principal cause because they found necrotic zones of bone in regions where neither heat nor monomer could have penetrated According to Willert and Frech (1976) the amounts of residual monomer released into the bone tissue will certainly be capable of causing tissue necrosis Several ex perimental temperature measurements in bone adjacent to polymerizing cement (as cited in section II) have not resulted in a conclusive opinion with respect to the thermal effect owing to the wide spread of results
A histological study concerning adverse side effects of bone cement in rabbits was published by Feith (1975) He concluded that reaming and residual monomer especially an overdose, both cause bone necrosis at the interface but that the principal causative factor is the heat of polymerizing. These experiments will be further discussed in section II

Later postoperatively the layer of necrotic bone is resorbed and replaced by soft tissue in which new bone is formed The structure of th s new bone layer s not ne e [illegible]
to that of the original [illegible]
trabecular shaped int[illegible]
bone is often lost and replaced by a more or less smooth bone layer
Also the new bone is not in direct contact with the cement because a fibrous tissue layer always remains This layer may be extremely thin and caused by a normal tissue reaction to the foreign body (Charnley 1970 1978) Often however, this layer is reported as quite thick and to appear on radiographs as a radioluscent demarcation line Willert and Puls (1972) measured the layer to be usually 0 1 to 1 5 mm thick Most authors believe that the occurrence of this thick layer is related to micromovements and stresses at the interface (e g Charnley 1970 Willert and Puls 1972 Willert *et al*, 1974 Vernon Roberts and Freeman 1977)
If a fibrous layer (radioluscent line) is abnormally thick or its thickness increases progressive ly it is usually regarded as a sign of forthcoming prosthesis loosening (see chapter 2)
The strength of the cement bone interface depends on the amo nt of [illegible]
locking [illegible]
faces usi[illegible]
The [illegible]
of [illegible]
di[illegible]
cancellou[illegible] crease of 100% n stren[illegible] mm
when the [illegible]
cement [illegible]

[illegible] ous y a fected by interface remodeling and the forma tion of fibrous tissue layers as d scussed previously

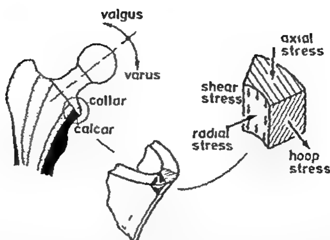

fig 1 7 An example of a hip endoprosthesis with a collar, to rest on the calcar bone rim Varus valgus position as well as stress components in the calcar region are indicated the axial stress component is a physiological one, the radial and shear stresses at the cement-bone interface and the circumferential (hoop)stresses in the bone, inflicted by the prosthesis, are quite unnatural

Bocco *et al* (1977) and Griss *et al* (1978) found a significant reduction in the incidence of calcar resorption when the (collarless) prosthesis was placed in valgus position (fig 1 7), compared to a fixation in varus position, thus changing the loading system relative to the fixation and also increasing the cement layer thickness on the medial side Although most experimental and theoretical studies, as will be reviewed in section III, support the advantages of a collar, there appears to be no clinical evidence as to its benefit (e g Charnley, 1977, 1978, Lee *et al*, 1977, Muller and Niederer, 1977) Significant data was published by Diehl (1975) and by Griss *et al* (1978) indicating that due to usually minor bone resportion at the collar calcar contact region and the formation of a soft intermediate tissue layer the collar will not be effective anyway

1 7 The cement bone interface

The cement bone interface is the key region for success or failure of the artificial joint replacement, many complications find their origin at this junction of biological and technical material Its initial shape depends on the bone structure more or less smooth if cortical bone forms the implant bed and rather wild if the implant bed consists of trabecular bone There is no chemical bond between the acrylic cement and the bone Mechanical interlocking between the cement and the trabecular bone is possible to an extent depending on a number of factors the viscosity of the cement mixture when inserted, the pressure applied to the cement mass, the cleanliness of the implant bed and dimensional changes of the cement
As already mentioned in paragraph 1 1, it has recently been advocated to insert the mixture early during a more liquid phase and to press the cement into the trabecular spaces using specially designed equipment and an intramedullary plug in the case of stem fixation (Markolf and Amstutz, 1976, Oh *et al*, 1978, Krause *et al*, 1979, Weber and Stuhmer 1979) It has also been advised to clean the implant bed after reaming using pulsating pressurized water flow (Narten *et al*, 1977, Halawa *et al*, 1978, Miller *et al*, 1978)
An optimal mechanical interlocking between cement and bone will be advantageous for an

Stuhmer (1976) reports a loosening incidence of 4 3% in 2577 patients who received a total hip replacement, only 10 6% of the material could be qualified as late results (more than 5 yrs follow up), 87.5% of the loosened cases occurred after 450 days postoperatively The loosening incidences reported in comparable follow up studies usually range between 0% and 7% with occasionally a higher number (e.g Amstutz *et al*, 1970, 1978, Bergstroem *et al*, 1973, Charnley and Cupic 1973, Lazanksy, 1973, Weber and Charnley, 1975, Eftekar *et al*, 1976, Slooff *et al*, 1976, Stuhmer, 1976, Witt and Hackenbroch, 1976, Rütt, 1977, Visuri *et al*, 1977)
Aseptic loosening occurs in all the various types of prostheses Because of the large number of parameters involved (design used, materials used, surgical procedures, individual properties and level of activity of the patients) statistical analyses usually do not result in significant relations between the parameters and the incidence of loosening.
In many series aseptic loosening is the complication most occurring but, although undesirable, an incidence of 7% cannot be called alarming However, in most patient reviews the number of postoperative years were relatively rather short and it is being shown in an increasing number of publications, that the number of artificial hip-joints that loosen aseptically rises sharply with the number of postoperative years, as opposed to septic loosening (due to infection) This was illustrated by an investigation of Witt and Hackenbroch (1976), who calculated average loosening incidences from publications concerning reviews on hip replacements carried out between 1963 and 1973 (table 2 1)

Postoperative period (years)	Average incidence of aseptic loosening	Average incidence of septic loosening
07 13	1 6%	2 4%
17 45	4 %	2 3%
5 95	8 %	3 3%

table 2 1 Average loosening percentages, septic as well as aseptic, calculated from various hip replacement reviews (after Witt and Hackenbroch, 1976)

Due to the progressively occurring incidence, aseptic loosening is considered as a very severe complication and many authors thus maintain that joint replacements should remain restricted to older patients (60 yrs and over) (e g Muller, 1974, Stuhmer, 1976)
Disturbing reports have been published recently on radiological reviews of patients who received a total hip replacement Beckenbaugh and Ilstrup (1978) reviewed 333 Charnley hip arthroplasties after 4 to 7 postoperative years They looked for roentgenographic evidence of loosening of the femoral component which they defined as significant subsidence of the prosthesis with respect to the bone They found this evidence in 24% of the cases Of the loosened cases 20% showed definite roentgenographic evidence of associated fracture in the cement The overall clinical results of the loosened group was poor, although only 8% had required re-operation as yet The authors ascribe the loosening principally to cement fracture, which will be progressive in their opinion, and ultimately require revision of all loosened hips
A comparable investigation was reported by Gruen and A[illegible]

[illegible] 7% these signs

CHAPTER TWO

COMPLICATION OF ARTIFICIAL-JOINT REPLACEMENT

2 1 Introduction

Results and complications of artificial joint replacement are usually studied in patient reviews The results of these reviews, or follow up studies, are becoming available in ever increasing numbers In the first studies published the number of postoperative follow up years was usually rather small, recently studies on large series of late results (more than 5 yrs postoperatively) have been reported, especially on hip replacement

The complications of artificial joint replacement are usually divided into three categories (Muller, 1976, Schulitz and Dustmann, 1976) (1) pre-operative complications (mentioned in chapter 1 1), (2) early complication (up to four weeks postoperative, including dislocation of the joint, haematoma, thrombosis, allergic reactions, early infection and a few others) and (3) late complications (including infection, aseptic loosening, mechanical failure of the implant components, bone fracture, ectopic bone formation, migration of the implant and a number of others) An extensive follow up study on 2256 patients who received total hip replacement was reported by Gschwend (1976) Postoperative complications were found in 10 68% of the cases, of which bone perforation (femur and acetabulum) accounted for approximately 8% and no other specific complication occurred in more than 1% of the cases Early complications were found in 29 42% of the cases, of which 15 32% were local, the largest group consisted of haematoma (8%) and infection (1 5%)
All these complications do not in general cause failure of the joint replacement, as opposed to deep infection, aseptic loosening (loosening without infection) and mechanical failure of the implant For deep infection, usually leading to re operation, incidences of 0 to 11% are reported in the literature (e g Green, 1976, Hunter and Dandy, 1977)
Aseptic loosening and implant failure are subjects of the present investigation and will be treated in somewhat more detail

2 2 Aseptic loosening

Aseptic loosening occurs when the implant loosens with respect to the bone by a cause other than infection Usually patients feel pain on load bearing and the loosening can be established by clinical and radiological examination and by using scintigraphy (Feith *et al*, 1976), although not always with certainty As a phenomenon it can either be fracture of the cement or a loosening of the cement bone interface, leading to movement between the

ther

hand induce implant fracture, this complication is treated separately
Loosening of the implant most often results in a revision operation The cause of the loosening is not always apparent, although its incidence is often found together with roentgenographically established cracks in the cement mantle, inadequate cementing (incomplete mantle), thick radioluscent lines, inadequate positioning, calcar resorption or a combination of these phenomena During the re operation fractioned cement or a thick layer of fibrous tissue are sometimes found

Although this is being contradicted by Charnley (1978), many investigators expect that the roentgenographic evidence indicates a forthcoming need for revision

Considerably less literature is available on other than hip joint replacements For the knee joint, loosening incidences have been reported of 4% to 30%, the higher numbers being representative of the hinged prostheses (Peterson, 1977, Freeman *et al*, 1978, Ducheyne *et al*, 1978, Lacey, 1978) Loosening incidences of 3% to 30% were reported for elbow prostheses, the high percentages certainly caused by the high torsional loading of the humeral component (Schlein, 1976, Nederpelt, 1978)

2 3 Implant failure and bone fracture

Mechanical failure of the artificial joint itself can either be due to fracture or plastic deformation of a component, while excessive wear may also be reckoned among the causes Fracture of a component is frequently reported as occurring in femoral stems of hip prostheses Martens *et al* (1974) reported six femoral stem fractures out of a series of 56 Charnley Muller total hip replacements (10 7%) All fractures were located in the middle third of the stem and could be ascribed to fatigue At least part of the fractures were preceded by fractures in the cement
Ducheyne *et al* (1975) reported two stem fractures in a series of 90 Charnley total hip replacements Both fractures occurred in the proximal part of the stem (at the curvature) and were preceded by plastic deformation Galante *et al* (1975) reviewed 21 articles concerning follow up studies of a total of 6,110 hip replacements and found that re operation due to fractured stems was needed in only 0 15% of the cases Charnley (1975) investigated 17 cases of fractured stems out of a series of approximately 6,500 total hip replacements (0 26%) He found that the incidence of stem fracture among patients over 76 kg in weight was 2 6% and for [illegible]
he considers erosion or calcar reso [illegible]
Collis (1977) reported 4 stem frac [illegible]
patients who weighed over 91 kg. [illegible] postoperative follow up period was 4 to [illegible] years All stem failures were preceded by cement fractures in the proximal medial region Rostoker *et al* (1978) investigated 34 fractured stems All fractures were found to be due to fatigue failure In all the fractured cases the patient exhibited at least one of the 'risk factors', which they define as high body weight, malpositioning lack of calcar support and roentgenographic signs of loosening They also found metallurgical defects in 31 of the fractured stems It should be remarked here that on detailed investigation no material will be found absolutely pure

Fractures of acetabular components of total hip prostheses are not [illegible]
literature Fractures of [illegible]
while finger jo [illegible]
mation (cold c [illegible]
(Walker 1977 [illegible]

increased progressively A radiographic analysis of 100 Charnley total hip replacements with a follow up of 5 to 7 years was carried out by Salvati *et al* (1976) They established clear radioluscent lines at the cement bone interface of the femoral component in 55% of the hips, 25% remained constant, 10% decreased and 21% gradually increased in thickness They established radioluscent lines in the acetabular component in 93% of the hips, the line remained stable in 41%, decreased in 23% and gradually increased in 29% of the cases Cement cracks they could only identify in 3% of the cases

Loosening of acetabular components of artificial hip joints is reported about as frequently as of femoral components, in some series its incidence is even higher (e g Dietschi *et al*, 1976)
A loosening incidence of approximately 20% of acetabular cups was reported by Visuri and Laurent (1977) in a series of 351 Charnley total hip replacements with 5 to 7 years follow up, of the remaining 80%, 29% showed roentgenographic signs of loosening, this being a radioluscent zone of 1 to 12 mm at the cement bone interface
In a series of 95 total hip replacements after 4 to 7 postoperative years, Maier *et al* (1977) report 14 7% roentgenographically and clinically established cases of acetabular cup loosenings, in addition they found 4 9% of only roentgenographically established loosenings

Much better results have been reported by Charnley (1978) In a series of 396 patients who received total hip replacement, with 12 to 15 years follow up, 0 25% had to be re-operated due to loose femoral components and 1 26% due to loose acetabular components For his total material of 10,000 total hip replacements he reports a revision percentage of 0 25% due to loose femoral or acetabular components A summary of some roentgenographical data concerning this series, as established in several investigations cited by Charnley (1978), is shown in table 2 II

Study No	1	2	3	4	5	6	7	8	9
hip replacements	138	106	6,649	141	190	169	216	547	115
postoperative years	7 8	9 10	3 14	8 11	3 8	8 11	1 6 2 6	8	12 15
Femoral component

cement fracture	–		1 5%	–		–	23 3%	8 6%	–
calcar resorption	–	99 9%		–	37 2%	70%	23 1%	–	95%
Acetabular component									
migration	1 4%	1 4%	–	9 2%	–	–	–	–	11%
no radioluscent line	–		–	31 3%		–	–	–	41%
moderate radioluscent line	–	–	–	60 3%	–	–	–	53 7%	34%

table 2 II Some results of radiographic reviews of total hip replacements (after Charnley, 1978)

In summarizing, it is found that the number of failed hip replacements increases late post operatively due to aseptic loosening Many patients although still asymptomatic, show roentgenographic evidences of loosening such as cement fractures, subsidence of the prosthesis and progressive radioluscent demarcation lines at the cement bone interface

Although this is being contradicted by Charnley (1978), many investigators expect that the roentgenographic evidence indicates a forthcoming need for revision

Considerably less literature is available on other than hip-joint replacements For the knee joint, loosening incidences have been reported of 4% to 30%, the higher numbers being representative of the hinged prostheses (Peterson, 1977, Freeman *et al*, 1978, Ducheyne *et al*, 1978, Lacey, 1978) Loosening incidences of 3% to 30% were reported for elbow prostheses, the high percentages certainly caused by the high torsional loading of the humeral component (Schlein, 1976, Nederpelt, 1978)

2 3 Implant failure and bone fracture

Mechanical failure of the artificial joint itself can either be due to fracture or plastic deformation of a component, while excessive wear may also be reckoned among the causes Fracture of a component is frequently reported as occurring in femoral stems of hip prostheses Martens *et al* (1974) reported six femoral stem fractures out of a series of 56 Charnley Muller total hip replacements (10 7%) All fractures were located in the middle third of the stem and could be ascribed to fatigue At least part of the fractures were preceded by fractures in the cement
Ducheyne *et al* (1975) reported two stem fractures in a series of 90 Charnley total hip

[illegible]

[illegible] stigated 17 cases of fractured stems out of a series of approximately 6,500 total hip replacements (0 26%) He found that the incidence of stem fracture among patients over 76 kg in weight was 2 6% and for patients over 89 kg in weight even 6 1% Besides weight he considers erosion or calcar resorption as the possible predominant factor in stem failure Collis (1977) reported 4 stem fractures out of 200 total hip replacements (2%), all in patients who weighed over 91 kg The postoperative follow up period was 4 to 6 years All stem failures were preceded by cement fractures in the proximal medial region Rostoker *et al* (1978) investigated 34 fractured stems All fractures were found to be due to fatigue failure In all the fractured cases the patient exhibited at least one of the 'risk factors' which they define as high body weight, malpositioning, lack of calcar support and roentgenographic signs of loosening They also found metallurgical defects in 31 of the fractured stems It should be remarked here that on detailed investigation no material will be found absolutely pure

[illegible]

data become available on the relat [illegible]
taking the 'risk factors' into accou [illegible]

CHAPTER THREE

OBJECTS AND METHODS OF THE PRESENT STUDIES

3 1 Introduction

Clinical and roentgenographic follow up studies, as discussed in the previous chapter, give valuable information on the adequacy of the treatment in general, the kinds and numbers of problems that may be encountered and the way in which complications manifest themselves Usually no definite relation can be found between a complication and its cause, and when it is found, it is mostly statistical and not causative, due to the many uncertain parameters involved in a joint replacement Especially with respect to such a treatment, however, a fundamental understanding of the relations between causes and effects of complications is of great importance It has been mentioned previously that an artificial joint has to perform without complications for the full postoperative life span This means that ten to fifteen years would have to pass before the data on the general adequacy of a specific design or procedure would be complete This is not a good basis for 'trial and error' procedures and hence in our opinion all available means to predict the performance of a prosthetic device should be applied However complicated the (biological) bone prosthesis structure is, it is certainly possible to acquire fundamental knowledge on certain aspects If, for example, a fundamental concept on the relation between the structural parameters and the purely mechanical performance of the prosthesis in the body can be developed this might not lead to an immediate answer to the question of the optimal design features since also other complicated aspects are involved, but it would at least provide a firm basis or no basis, for a part of the arguments commonly used in solving this problem and it would at least extend the available means for a long term performance prediction

In orthopedic research studies of animal or laboratory models are often applied Another method that is not very common is the use of theoretical or mathematical models For certain research objects with respect to some problems of artificial joint replacement, too, the use of these methods have many advantages (Huiskes and v Heugten, 1974) In these methods the properties of the system to be investigated are described mathematically and, by using theories are interrelated in formulas that describe the system behavior One of the advantages of such theoretical analyses is the possibility to investigate influences of parameter [illegible]
between [illegible]
will be use[illegible]
of artificial [illegible] a stress analysis of intramedullary fixated prostheses principally focussed on the hip joint and a heat cond[illegible]
[illegible]
possibilities evolves [illegible] experiments an additional dimension in research

Occasionally, plastic deformed metal intramedullary stems are also encountered Recently a case of thermal deformation of a polyethylene tibial component of an artificial knee joint has been reported (Volz and Gradillas, 1978) The authors believe that such a deformation, caused by the polymerization heat of the acrylic cement, occurs more often and they found some evidence of it in several roentgenograms

There is no doubt that prostheses components are subject to wear in the body, which does not necessarily have to present a problem However, if the wear is excessive to an extent that it can no longer perform its function, it will result in failure Much research has been and is being done on wear of various biomaterials (e g Charnley and Halley, 1975, Walker, 1977, Swansson and Freeman, 1977)
The wear rates of the materials presently used are such that the wear in itself appears to present no serious problems This might be different, however, if younger patients received joint replacements

Fracture of the bone, postoperatively, is not a complication often encountered after artificial joint replacement In a series of 5400 total hip arthroplasties McElfresh and Coventry (1974) reported 10 postoperative bone fractures, 6 of which were in the femur, 3 in the acetabulum and one in both The acetabular fractures were not related to the hip replacement In some of the femoral fractures defects of the cortex due to screw holes or misdirected reaming were apparent
Scott *et al* (1975) also reported occasionally occurring femoral fractures, always related to cortical defects near the prosthesis stem tip

A bone failure mode' with a higher incidence, already mentioned in chapter 2 2, is the gradual sinking of a component through the bone Especially protrusion or migration of the artificial head or the cup of the hip joint through the acetabulum (e g Hoogbergen *et al*, 1975, Charnley, 1978) and sinkage of the tibial knee component in the tibia (e g Walker, 1977, Freeman *et al*, 1978) occur sometimes The protrusion may be caused by interface bone remodeling, stress (fatigue) fractures of the subchrondal spongeous bone or a combination of both

CHAPTER THREE

OBJECTS AND METHODS OF THE PRESENT STUDIES

3 1 Introduction

Clinical and roentgenographic follow up studies, as discussed in the previous chapter, give valuable information on the adequacy of the treatment in general, the kinds and numbers of problems that may be encountered and the way in which complications manifest themselves Usually no definite relation can be found between a complication and its cause, and when it is found, it is mostly statistical and not causative, due to the many uncertain parameters in volved in a joint replacement Especially with respect to such a treatment, however, a funda mental understanding of the relations between causes and effects of complications is of great importance It has been mentioned previously that an artificial joint has to perform without complications for the full postoperative life span This means that ten to fifteen years would have to pass before the data on the general adequacy of a specific design or procedure would be complete This is not a good basis for trial and error' procedures and hence in our opinion all available means to predict the performance of a prosthetic device should be applied However complicated the (biological) bone prosthesis structure is, it is certainly possible to acquire fundamental knowledge on certain aspects If, for example, a fundamental concept on the relation between the structural parameters and the purely mechanical performance of the prosthesis in the body can be developed, this might not lead to an immediate answer to the question of the optimal design features since also other com plicated aspects are involved but it would at least provide a firm basis, or no basis, for a part of the arguments commonly used in solving this problem and it would at least extend the available means for a long term performance prediction

In orthopedic research studies of animal or laboratory models are often applied Another method that is not very common, is the use of theoretical or mathematical models For certain research objects with respect to some problems of artificial joint replacement, too, the use of these methods have many advantages (Huiskes and v Heugten, 1974) In these methods the properties of the system to be investigated are described mathematically and, by using theories are interrelated in formulas that describe the system behavior One of the advantages of such theoretical analyses is the possibility to investigate influences of parameter changes and in this way acquiring a fundamental comprehension of relat one

possibilities evolves ... experiments an additional dimension in research

3 2 Heat conduction analyses

As was discussed in paragraph 1 7, thermal damage due to the polymerization heat of acrylic cement is regarded as a possible factor contributing to necrosis of the bony implant bed It was the object of the analysis presented in section II to establish whether the tem perature values in the bone, during implant fixation, may be such as can cause thermal damage and, if so, what measures can be taken to reduce the chances of thermal damage

Between cause (heat of polymerizing) and effect (bone temperature) there is a relation that depends on many parameters The heat of polymerizing itself depends on the amount of monomer in the mixture and hence on its composition

If the cement mass were completely isolated from its neighborhood, the temperature rise (ΔT) could easily be calculated from $Q = C\Delta T$, where Q denotes the total amount of poly merization heat and C the heat capacity As the cement mass is in contact with its adjoining materials, implant and bone, heat conduction occurs during and after the polymerization process Hence, on one hand the rate of heat generation in the cement mass depends on the polymerization rate, while on the other the rate of heat transport depends on the heat conduction properties of the cement, the interface, the implant and the bone By applying approximative mathematical descriptions of these properties and using heat conduction theory, this process can be described in a mathematical (computer) model With this model the temperature as a function of time can be calculated at any point of the structure, given the parameters that describe the following properties

- the geometry of the implant, the cement mass and the bone,
  the heat capacities and the thermal conductivities of these materials,
- the cement bone interface thermal conductivity,
- the bone surface heat loss,
- the polymerization rate,
- the cement composition

In section II such a model will be used to predict the time and location dependent tempe ratures during fixation of artificial joints The calculated temperature values are compared with thermal damage threshold levels in order to estimate the chances of bone necrosis occurring By varying the system parameters, their influences on the temperature values are investigated from which quantitative guidelines for composition and application of the cement can be derived

3 3 Stress analyses

The stress analyses, presented in section III, are confined to intramedullary fixated prostheses and focussed especially on the hip joint, although some results are valid for these systems in general

As was discussed in chapter 2, many complications of joint replacement are or may be related to stresses in the bone prosthesis structure Certainly stem, cement and bone fractures are caused by locally exceeding the (fatigue) strength of the materials Although definite causes for interface bone remodeling, development of fibrous tissue layers, calcar bone resorption, implant migration and disuses osteoporosis are as yet unknown, there is some evidence that these phenomena are, at least to some extent, stress related as well and thus it appears to be beneficial to provide a system in which the stress pattern is smooth and the stresses on and in bone are as natural as possible

For given joint forces the stress distribution in the [illegible] the bone, in the cement mantle

and at the interfaces depends on the geometry of the implant (for example stem length, thickness, taper, etc), the geometry of the cement mantle (for example its thickness) and the geometry of the bone, on the mechanical properties of the materials (for example their modulus of elasticity) and on the mechanical interface conditions By applying theories of continuum mechanics these properties can be described mathematically and interrelated in mathematical models With such models the stress values in the system can be approximated for given joint loading

It was the object of the analysis described in section III to contribute to better understanding of the relations between the geometrical and materials properties of the system components on one hand and the stresses in the system that result from a specific joint loading on the other To accomplish this, simplified mathematical models of the intramedullary fixation structure were studied, using various methods Also, relatively simple formulas were derived that roughly approximate to the most important stress values As will be shown in section III, with these formulas a direct relation can be established between the most important design and material parameters and some aspects of the mechanical performance of the system

3 2 Heat conduction analyses

As was discussed in paragraph 1 7, thermal damage due to the polymerization heat of acrylic cement is regarded as a possible factor contributing to necrosis of the bony implant bed It was the object of the analysis presented in section II to establish whether the temperature values in the bone, during implant fixation, may be such as can cause thermal damage and, if so, what measures can be taken to reduce the chances of thermal damage

Between cause (heat of polymerizing) and effect (bone temperature) there is a relation that depends on many parameters The heat of polymerizing itself depends on the amount of monomer in the mixture and hence on its composition
If the cement mass were completely isolated from its neighborhood, the temperature rise (ΔT) could easily be calculated from $Q = C\Delta T$, where Q denotes the total amount of polymerization heat and C the heat capacity As the cement mass is in contact with its adjoining materials, implant and bone, heat conduction occurs during and after the polymerization process Hence, on one hand the rate of heat generation in the cement mass depends on the polymerization rate, while on the other the rate of heat transport depends on the heat conduction properties of the cement, the interface, the implant and the bone By applying approximative mathematical descriptions of these properties and using heat conduction theory, this process can be described in a mathematical (computer) model With this model the temperature as a function of time can be calculated at any point of the structure, given the parameters that describe the following properties
- the geometry of the implant, the cement mass and the bone,
- the heat capacities and the thermal conductivities of these materials,
- the cement bone interface thermal conductivity,
- the bone surface heat loss,
- the polymerization rate,
- the cement composition

In section II such a model will be used to predict the time and location dependent temperatures during fixation of artificial joints The calculated temperature values are compared with thermal damage threshold levels in order to estimate the chances of bone necrosis occurring By varying the system parameters, their influences on the temperature values are investigated from which quantitative guidelines for composition and application of the cement can be derived

3 3 Stress analyses

The stress analyses, presented in section III, are confined to intramedullary fixated prostheses and focussed especially on the hip joint, although some results are valid for these systems in general
As was discussed in chapter 2, many complications of joint replacement are or may be related to stresses in the bone prosthesis structure Certainly stem, cement and bone fractures are caused by locally exceeding the (fatigue) strength of the materials Although definite causes for interface bone remodeling, development of fibrous tissue layers, calcar bone resorption, implant migration and disuses osteoporosis are as yet unknown, there is some evidence that these phenomena are, at least to some extent, stress related as well and thus it appears to be beneficial to provide a system in which the stress pattern is smooth and the stresses on and in bone are as 'natural as possible
For given joint forces the stress distribution in the stem, in the bone, in the cement mantle

CONTENTS

Geometry and materials quantities

m	kg	mass
V	m^3	volume
ν	–	volume fraction (see paragraph 5.1)
P/L	gr/cc	powder to liquid ratio
r_u	m	outer bone radius
r_i	m	*inner* bone radius
s	m	cement layer thickness
r_s	m	implant stem radius
μ	~	weight ratio m_{ap}/m_p

Materials properties

λ	J/msec°C	thermal conductivity
C	J/m³°C	heat capacity
c	J/kg°C	specific heat
ρ	kg/m³	density

Heat generation

$\Phi(r,z,t)$	J/m³sec	heat source
$\Phi_n(r,z)$ $\Phi_{n-1}(r,z)$, etc	J/m³sec	heat source at time t_n, t_{n-1}, etc
Q	J/m³	heat generation per unit volume of acrylic cement
Q_t	J/kg	heat generation per unit mass of monomer
ρ_m	kg/m³	density of monomer
ν_m	–	volume fraction of actually polymerizing monomer in the cement mixture
$p(t)$	–	polymerized fraction of the monomer (polymerization function)
t_r	sec	retardation time (see paragraph 5.2)
τ	sec	polymerization time (see paragraph 5.2)
θ_p	sec^{-1}	maximal polymerization rate

Others

$q(r,z,t)$	J/m²	heat flow
α	J/m²sec°C	surface conduction and convection coefficient
β_{kl}	J/m²sec°C	thermal contact ('interface') conductivity from material k to material l
t_e	sec	time of exposure
$T_n(t_e)$	°C	threshold temperature for cell necrosis
$T_d(t_e)$	°C	threshold temperature for vascular damage

LIST OF SYMBOLS

General

t	sec	time
t_n, t_{n-1}, etc	sec	times
Δt	sec	time step ($t_n - t_{n-1}$)
r, z	m	coordinates (cylindrical system)
x, z	m	coordinates (plane rectangular system)

Temperature

$T(r,z,t)$	°C	temperature
$T_n(r,z)$, $T_{n-1}(r,z)$, etc	°C	temperature at time t_n, t_{n-1}, etc
$T_a(r,z)$	°C	ambient temperature
$T_0(r,z)$	°C	initial temperature
T_{0j}	°C	initial temperature of material j (for possibilities of j see under 'indices')
$\Delta T(r,z,t)$	°C	temperature drop
$T_{max}(r,z)$	°C	maximal temperature
T_b	°C	maximal bone temperature
ΔT_b	°C	maximal bone temperature increase (T_b-37°C)
T_c	°C	maximal cement temperature
ΔT_c	°C	maximal cement temperature increase ($T_c - T_{0c}$)
$\delta(t)$	mm	penetration depth (in the bone) of an isotherm
δ_m	mm	maximal penetration depth (in the bone) of the 50°C isotherm

Indices

The indices used for the parameters describing the materials properties and quantities (and some other parameters) refer to

c — cement
i — implant
b — bone
p — polymer
m — the actually polymerizing monomer
rm — residual monomer
po — powder
li — liquid
ap — additives to the polymer
am — additives to the monomer
ac — additives to the cement mixture

Authors	maximal cement bone 'interface temperature'	conditions
Homsy *et al* (1972)	70 - 90°C	dog femurs, various bone cements
Meyer et *al* (1973)	70°C	human femurs, total hip replacement
Biehl et *al* (1974)	47°C	average value, human femur, total hip replacement
Labitzke and Paulus (1974)	45°C	average value, human femur, total hip replacement

table 2 1 Results of some temperature measurements in vivo at the cement bone interface, as reported in the literature

conclusions as [illegible] whether the reported temperatures are those of the cement or the bone

Another kind of experiment in vivo was reported by d'Hollander *et al* (1976) who measured temperatures during total hip replacement at the outside surface of the femur and in the bloodstream of the ipsilateral iliac vein The first quantity increased from an average of 31 5°C to one of 34 1°C, the latter remained practically stable at an average of 34 5°C

2.2 Temperature measurements in vitro

[illegible] in the centre [illegible] ry They [illegible] mparable [illegible] ial temperature values of up to 134°C, it is not clear what causes the discrepancy [illegible] se results and those of Ohnsorge and Kroesen (1969) Hupfauer and Ulatowski (1972) in addition measured temperatures in plates of bone cement, using thermography Although th[illegible] method [illegible] not very accurate, the results clearly indicate that the temperature values were distributed rather inhomogeneously over the surface of the plate
Ohnsorge and Goebel (1969, 1970) measured temperatures at different locations during fixation of a hip endoprosthesis in a cadaveric femur An example of their results, which are rather illustrative, is shown in fig 2 1 They repeated this experiment after pre-cooling the prosthesis to 0°C The maximal 'interface temperature' in this case was about 20° less However, due to pre cooling, the setting time of the cement approximately doubled, which probably results in inferior mechanical properties (Oest *et al*, 1975)
[illegible] Teflon [illegible] They [illegible] described in chapter [illegible]
Other temperature measurements, in various circumstances, were conducted by de Wijn (1974) Jefferiss *et al* (1975), Cameron *et al* (1975), Dipisa *et al* (1976), Debrunner *et al*

CHAPTER ONE

INTRODUCTION

In this section a mathematical (computer) model will be presented for the analysis of the heat generation and conduction process of self curing acrylic cement in situ The model will be used to simulate this process as it occurs during fixation of artificial joints, to predict time and location dependent temperature values in the bone prosthesis system The results will be compared with data on thermal damage threshold levels of bone tissue, as published in the literature, in order to assess the possibility of thermal necrosis The second chapter contains a review of the literature on previous work The third chapter treats possible threshold levels for thermal bone necrosis and in the fourth the model, its assumptions and the mathematical methods of solution will be discussed In chapter five values for parameters describing the heat generation and conduction properties of the system, to be used in the model calculations, will be estimated on the basis of a thorough review of the literature In order to evaluate the model and the method of analysis, two experiments described in the literature are simulated, as described in chapter six In chapter seven the model is actually used to simulate the thermal behavior of the cement during fixation of intra medullary implants To establish the influences of the system properties, a parametric analysis with respect to this bone prosthesis system was carried out and will be described also in this chapter Chapter eight discusses the use of the acrylic cement during acetabular cup fixation and in chapter nine various measures that can be taken to reduce the chances of thermal bone necrosis are evaluated as to their effectiveness

CHAPTER TWO

A SHORT REVIEW OF THE LITERATURE ON EARLIER WORK

2 1 Temperature measurements in vivo

Several measurements of temperatures in the cement bone contact region (the interface) in vivo have been reported in the literature, some of which are summarized in table 2 1
All investigators used thermocouples
Although these results give some indication of the temperature values that might occur, there is some doubt as to their reliability The heat conduction process will certainly be affected by the thermocouples and, moreover, the cement bone interface is a region rather than a well defined location where a steep temperature gradient probably occurs Hence, the 'cement bone interface temperature' is a badly defined quantity and measurements in this region will be highly sensitive to the thermocouple locations It is thus hard to draw

Such a simple model could be very valuable in roughly evaluating influences of some parameters however, the parameter values they applied in their model for the heat capacity and conductivity properties of the materials were quite unrealistic

D'Souza *et al* (1977) calculated transient temperatures in an axisymmetric slice consisting of a metal core and a bony ring with acrylic cement in between Few data were published but they claim a good agreement between the results and those of verification experiments

A comparable analysis was carried out by Swenson *et al* (1976), who studied the influences of the cement layer thickness on the maximal bone temperatures In this case, too, few data were published

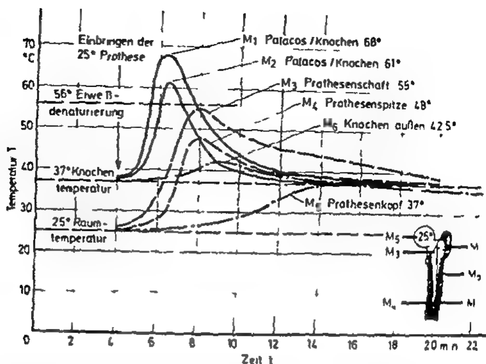

Fig 2 1 Temperatures as a function of time at 6 locations in a cadaveric femur prosthesis system during the polymerization of the acrylic cement (reproduced with permission of Ohnsorge and Goebel, 1969)

(1976), Lee and Turner (1977) and Seidel *et al* (1977) Varieties in commercial brands, influences of initial temperatures, 'heat sink' additives and the polymerization rate were studied in some of these experiments

Experimental conditions were usually much better defined in these laboratory measurements compared to the experiments in vivo and useful information was obtained on the thermal behavior of the curing acrylic cement Because of the empirical character of the experiments, however, it is often difficult to apply the results to the situation in vivo and derive general criteria for the use of the cement, as so little is known about the influences of the different geometrical and material parameters Moreover, also in these laboratory experiments the 'interface temperatures' are unreliable, due to the thermocouple influence and the steep temperature gradient in this region
It has become clear from these experiments that the properties and the geometry of the adjoining materials have a significant influence on the temperature values and that the heat generation process can be affected by changing the composition of the cement mixture
It was also found that the initial temperature of the cement greatly influences the setting time

2 3 Theoretical studies

A theoretical study of the heat conduction process in acrylic cement was carried out by Jefferiss *et al* (1975) Their model is very simple, assuming one dimensional heat flow and neglecting the time dependent character of the heat generation process (a homogeneous initial temperature was assumend in the cement layer)

Such a simple model could be very valuable in roughly evaluating influences of some para meters, however, the parameter values they applied in their model for the heat capacity and conductivity properties of the materials were quite unrealistic

D'Souza *et al* (1977) calculated transient temperatures in an axisymmetric slice consisting of a metal core and a 'bony' ring with acrylic cement in between Few data were published but they claim a good agreement between the results and those of verification experiments

A comparable analysis was carried out by Swenson *et al* (1976), who studied the influences of the cement layer thickness on the maximal bone temperatures In this case, too, few data were published

THRESHOLD LEVELS FOR THERMAL BONE NECROSIS

After temperature values in bone have been measured or calculated, they have to be compared to a thermal damage criterion in order to estimate the chances of thermal necrosis, such a criterion is called the temperature threshold level for thermal damage (here denoted by T_n(°C)) In the literature on thermal behavior of acrylic cement, as discussed in the previous chapter, the threshold temperatures of collagen denaturation (56°C, Lehnartz (1959), 60°C, Viidik (1972), 70°C, Labitzke and Paulus (1974)) is usually taken as a criterion It has been established, however, that collagen is more temperature resistent than the protoplasm proteins (Lundskog, 1972) In this respect Leach *et al* (1943), on the basis of an extensive review, concluded that all endothelial cells die at a temperature of 47°C and over and also that temperatures between 42°C and 47°C, provided they are maintained long enough, may harm the cells This was confirmed by Moritz (1947) and Sevitt (1957)
Not only the temperature, but also the time during which the tissue is exposed determines the threshold level for thermal damage, hence, this level will be time dependent ($T_n = T_n(t_e)$ where t_e is the time of exposure) Investigations on time dependent threshold curves for epithelial cells were carried out by Moritz and Henriques (1947) They established, for instance that a temperature of 70°C will kill the cells immediately, that a temperature of 55°C will do so after a 30 seconds, but that a temperature of 45°C would have to be maintained for more than 5 hours to harm the cell Based on these results they constructed a temperature threshold curve ($T_n(t_e)$) for epithelial cells Their results have been confirmed later by other investigators (as cited by Lundskog 1972), for human as well as for porcine skin Kuhl *et al* (1954) found a slightly lower threshold level for epidermal necrosis (52°C after 30 seconds) in mice experiments and ascribe the deviation to differences in the species

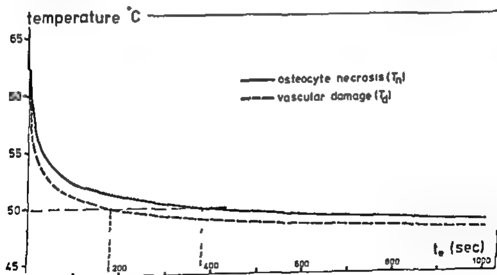

Fig 3 1 ... *threshold level for vascular damage (T_d), as constructed ... a from the same authors t_e denotes the exposure time*

Lundskog (1972), in extensive histochemical studies on rabbits, roughly confirmed the threshold curve reported by Moritz and Henriques (1974) but established a lower threshold value for the bone cells, using heated implants (50°C after 30 seconds) He also indicated that much higher temperatures (up to 70°C) are needed before damage is done to the regenerative capacity of the bone tissue

Due to the many parameters that are involved in experiments in vivo and also because of uncertainties as to the possible surgical trauma brought about by implants the results of Lundskog cannot be considered as significantly different from those of Moritz and Henriques

Because the threshold curve published by the last named authors gives a good impression of both the temperature and the time aspects of thermal necrosis, it will be used here as a criterion for judging possible osteocyte necrosis

Moritz and Henriques (1947) also reported that there is functional damage to the vascularity after exposure periods that are about 40 to 60% shorter compared to the necrosis level of epithelial cells From this the vascular damage temperature threshold curve ($T_d(t_e)$) can be constructed Graphs for both T_n and T_d are shown in fig 3 1 It should be kept in mind, however, that cell necrosis has also been reported for lower temperatures (Lundskog, 1972)

CHAPTER FOUR

A THEORETICAL ANALYSIS OF HEAT GENERATION AND CONDUCTION

4 1 Assumptions and simplifications

To develop a mathematical model for simulating the process of heat generation and conduc tion, the relevant properties of the system must be described with parameters In order to perform actual calculations these parameters must be given values Relatively little is know about parameter values for heat generation, heat conduction and heat capacity properties of the materials in the bone prosthesis system Hence, a very refined model can not actually be used It is also open to question in view of complicated aspects (for instance the structur of bone, the vascularity, the geometry of the cement bone interface and the consistency of the cement mantle, all of which vary considerably from patient to patient) whether a very refined model would be justified Therefore a number of assumptions are made In order to be able to analyse the thermal behavior of the cement using the classical heat conduction theory it is assumed

- no material transport takes place in the system, and the materials are incompressible,
- the local heat loss by conduction and convection at the boundary of the system (usually the outer bone surface) is proportional to the difference in the local boundary tempera ture and a constant local ambient temperature, or the boundary temperature is equal to this ambient temperature

To simplify the analysis in view of the above mentioned aspects of the complicated bone prosthesis system, it is assumed that

- the thermal properties of implant, cement and bone are isotropic,
- the cement mixture is homogeneous,
- the heat conduction and capacity properties of the materials are independent of the temperature
- the heat generation as a function of time is independent of the temperature,
- the cement bone interface is smooth and the local heat transport across the interface is proportional to the local difference in temperature between the two materials

Obviously the results of the model calculations can only predict the temperature values in the real system by approximation Since influences of inaccuracies can be evaluated by parametric analyses, the model can still conveniently by used to obtain reliable approxima tive data, if gross effects are not neglected due to the assumptions The most serious assump tion in this respect as follows from the experimental data discussed in paragraph 2 2 is neglecting the temperature influences on the time-dependent heat generation necessary because a mathematical description of this influence is not available There are indications however (Naylor and Billmeyer, 1953, Meyer *et al*, 1973 Debrunner *et al*, 1976) that this influence, which mainly affects the setting time of the cement is relatively slight provided the initial temperature variance of the cement is kept within a small range

The bone prosthesis systems to be investigated are approximated by axisymmetric or plane geometry, which simplifies the solution procedures to a great extent and will in most cases give quite realistic results It should be remarked here that the previously mentioned assumptions would not justify a true three dimensional model, as a model requires a certain balance in the description of all aspects Furthermore, if the aim is to perform extensive parametric analyses and evaluate the influences of the most important system parameters in

order to develop a fundamental concept of the heat conduction process, the number of parameters in the model have to be kept restricted

4 2. Mathematical formulation

In consequence of the previously mentioned assumptions, the process of heat generation and cond... [illegible]

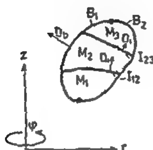

fig 4 1 An arbitrary axisymmetric structure consisting of three materials (see text)

materials (M_1, M_2 and M_3) in contact at the interfaces (I_{12} and I_{23}) with boundaries B_1 and B_2, the time and location dependent temperature $T(r,z,t)$ can be described by

$$\frac{\partial}{\partial r}(\lambda r\frac{\partial T}{\partial r}) + \frac{\partial}{\partial z}(\lambda r\frac{\partial T}{\partial z}) - Cr\frac{\partial T}{\partial t} + r\Phi = 0 \qquad \text{in } M_1, M_2 \text{ and } M_3 \tag{4 1}$$

$$\lambda(\underline{n}, \text{grad}T) = -\alpha(T - T_a) \qquad \text{on } B_1 \tag{4 2}$$

$$T = T_a \qquad \text{on } B_2 \tag{4 3}$$

$$\lambda(\underline{n}, \text{grad}T) = -\beta(T - T_{adj}) \qquad \text{on } I_{12} \text{ and } I_{23} \tag{4 4}$$

where

t	time	(sec)
r,z	coordinates	(m)
$T(r,z,t)$	temperature	(°C)
$\Phi(r,z,t)$	heat source	(J/m^3 sec)
$\lambda(r,z)$	thermal conductivity	(J/msec°C)
$C(r,z)$	heat capacity	(J/m^3°C)
$\underline{n}(r,z)$	normal vector on boundary (b) or interface (i)	(-)
$\alpha(r,z)$	surface conduction and convection coefficient	(J/m^2sec°C)
$T_a(r,z)$	ambient temperature	(°C)

$\beta(r\ z)$	interface conductivity	$(J/m^2 sec°C)$
$T_{adj}(r\ z\ t)$	temperature of the adjoining material	(°C)

with initial conditions $T(r,z\ 0) = T_0(r,z)$ in M_1, M_2 and M_3 and on B_1, B_2 I_{12} and I_{23}

For plane geometry (x z plane), assuming no heat flow in the direction perpendicular to th x z plane the differential equation transforms into

$$\frac{\partial}{\partial x}(\lambda\frac{\partial T}{\partial x}) + \frac{\partial}{\partial z}(\lambda\frac{\partial T}{\partial z}) - C\frac{\partial T}{\partial t} + \Phi = 0$$

while all other equations remain as they are, replacing r by x

4 3 Method of solution

The differential equation presented in the previous paragraph can not be solved analyticall in general Hence, numerical (computer) methods have to be used In order to be able to take arbitrary geometry into account, Finite Element Methods (FEM) offer the best optio Different solution procedures are available (e g Zienkiewicz 1977) that can be divided int those that apply FE discretization in coordinates as well as in time, and those that apply FE discretization in geometry and a Finite Difference Method for discretization in time Because a computer program for the solution of elliptical differential equations (such as the heat conduction equation for steady state) in an arbitrary two dimensional region base on FEM was available (Brekelmans 1975), the latter method was chosen
The temperature as a function of time is discretized according to

$$\frac{\partial}{\partial t}T(t) \approx \frac{1}{\Delta t}\{T(t) - T(t-\Delta t)\} \qquad \text{(backward difference)}$$

where Δt denotes a time step

By introducing the notation $T_n(r\ z) = T(r\ z\ t_n)$ $T_{n-1}(r\ z) = T(r\ z\ t_{n-1})$ $\Phi_n(r\ z) = \Phi(r\ z\ t_n)$ etc where $\Delta t = t_n - t_{n-1}$ the equations (4 1) through (4 4) are approximated by respectivel

$$\frac{\partial}{\partial r}(\lambda r\frac{\partial T_n}{\partial r}) + \frac{\partial}{\partial z}(\lambda r\frac{\partial T_n}{\partial z}) - \frac{C}{\Delta t}rT_n + \frac{C}{\Delta t}rT_{n-1} + r\Phi_n = 0 \qquad \text{in } M_1\ M_2\ M_3 \qquad (4\ 5)$$

$$\lambda(\underline{n},\text{grad}T_n) = -\alpha(T_n - T_a) \qquad \text{on } B_1 \qquad (4\ 7)$$

$$T_n = T_a \qquad \text{on } B_2 \qquad (4\ 8)$$

$$\lambda(\underline{n},\text{grad}T_n) = -\beta(T_n - T_{adj\ n}) \qquad \text{on } I_{12} \text{ and } I_{23} \qquad (4\ 9)$$

(4 5) is essentially an elliptical differential equation in T_n The available computer program for the solution of such an equation and the appropriate boundary conditions (Brekelmans 1975) was adapted to suit a step by step procedure in which for each step
$(\frac{C}{\Delta t}rT_{n-1} + r\Phi_n)$ is a given quantity calculated from the previous step (Huiskes 1977)

This strategy could conveniently be followed by using the backward-difference formula for time discretization. The application of this formula results in an unconditionally stable procedure according to Wilson *et al* (1966, 1974), while the accuracy depends on the time step dimension. In the computer program the time step is taken as constant, because this greatly economizes the computer procedure. The solution procedure cannot be qualified as efficient and better methods in this respect may be found in the literature (e.g. Zienkiewicz, 1977). However, under the circumstances this choice has proved to be quite convenient and has given excellent results, provided the time step dimension was small enough, as was established in a number of test problems with known solutions (Huiskes, 1977, 1979b).
The elemen[illegible] n an

CHAPTER FIVE

REVIEW OF THE LITERATURE ON THERMAL PROPERTIES

5 1 The composition of the acrylic cement

The acrylic cement mixture is composed of polymer powder (PMMA) and monomer liquid (MMA) The composition of the mixture is expressed in the P/L ratio (gr polymer/cc mono mer), which is usually around 2 An initiator is added to the powder and possibly radiopaque ($BaSO_4$ or ZrO_2) fillers or antibiotics A stabilizer and a catalyzer are added to the liquid The powder consists to approximately 99% of pure polymer, if no radiopaque or antibiotic additives are applied, and the liquid to approximately 97% of pure monomer After poly merizing, about 2 5% residual monomer remains present in the cement (Charnley, 1970, de Wijn, 1974, Oest *et al*, 1975)
For convenience in later use, the following quantities are defined

m_c =	mass of the cement mixture	(kg)
V_c =	volume of the cement mixture	(m^3)
ρ_c =	apparent density of the cement mixture	(kg/m^3)

and further

m_i =	mass of a component	(kg)
V_i =	volume of a component	(m^3)
ρ_i =	density of a component	(kg/m^3)
ν_i =	volume fraction of a component ($\nu_i = V_i/V_c$)	

where i denotes p (polymer), m (the part of the monomer that actually polymerizes), rm (residual monomer), ap (additives to the polymer powder), am (additive to the monomer liquid), ac (additives to the cement mixture), po (powder component), li (liquid component)
The fraction of the monomer that actually polymerizes in the mixture can be calculated from

$$\nu_m = \frac{\rho_{po}}{\rho_{po} + P/L \times 10^3} + \nu_{rm} - \nu_{am} \qquad (5\ 1)$$

The density of the polymer is reported as $\rho_p = 1\ 18 \times 10^3 kg/m^3$ (Charnley, 1970) and $P/L \approx 2$, if it is assumed that the residual monomer and the additives to the liquid each comprise approximately 3% of the liquid component, it follows that $\nu_{rm} + \nu_{am} \approx 0\ 02$ The monomer fraction ν_m for given P/L ratio can be evaluated from fig 5 1, for which formula (5 1) was used
If a third component (ac) is added to the powder liquid mixture, the monomer fraction in the three component mixture can be calculated from

$$\nu_m = \nu'_m (1 - \nu_{ac}) \qquad (5\ 2)$$

where ν'_m denotes the monomer fraction in the original two component mixture
This formula (5 2) will be used in chapter 9

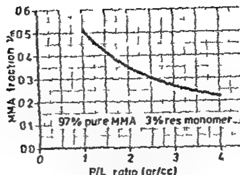

fig 5.1 Graphical representation of the relation between the P/L ratio and the actually polymerizing monomer volume fraction ν_m

5.2 Heat generation in acrylic cement

Heat is generated in the cement mass during the curing process, due to the exothermic polymerization reaction of the monomer. The total amount of heat generated per unit volume (Q) depends on the amount of monomer in the mixture and on the total amount of heat generated by the monomer per unit mass (Q_t).
It is obvious that both quantities are related by

$$Q = \nu_m \rho_m Q_t \qquad (J/m^3) \qquad (5.3)$$

It has been reported that $Q_t \approx 5.4 \times 10^5$ J/kg (e.g. Trommsdorf, 1963) and $\rho_m \approx 0.94 \times 10^3$ kg/m^3 (e.g. Charnley, 1970).

As the heat generated per unit time depends directly on the breakage of the double bond in the MMA molecules and hence on the amount of MMA molecules linked to PMMA per unit time, the heat source or heat generation function $\Phi(t)$ is proportional to the rate of polymerizing.
The polymerization process is, for our purpose, described by the polymerization function $p(t)$ $(0 \leq p \leq 1)$, giving the fraction of the monomer that has polymerized at a certain time. Hence it follows that

$$\Phi(t) = \nu_m \rho_m Q_t \frac{dp}{dt} \qquad (J/m^3 sec) \qquad (5.4)$$

The polymerization function can be measured by using light refraction methods (e.g. Naylor and Billmeyer, 1953) or by me[illegible]
method was used by de [illegible] of

bone cements [illegible] 200 - 400 sec for
It is assumed here that the curve shown in fig. 5.2 is in dimensionless form valid for all bone cements, this curve is described by $p_1 = p_1(t - t_r/\tau)$, $t \geq t_r$, and is in this form only influenced by t_r and τ.

CHAPTER FIVE

REVIEW OF THE LITERATURE ON THERMAL PROPERTIES

5 1 The composition of the acrylic cement

The acrylic cement mixture is composed of polymer powder (PMMA) and monomer liquid (MMA) The composition of the mixture is expressed in the P/L ratio (gr polymer/cc monomer), which is usually around 2 An initiator is added to the powder and possibly radiopaque ($BaSO_4$ or ZrO_2) *fillers or antibiotics A stabilizer and a catalyzer are added to the liquid* The powder consists to approximately 99% of pure polymer, if no radiopaque or antibiotic *additives are applied*, and the liquid to approximately 97% of pure monomer After polymerizing, about 2-5% residual monomer remains present in the cement (Charnley, 1970, de Wijn, 1974, Oest *et al*, 1975)

For convenience in later use, the following quantities are defined

m_c =	mass of the cement mixture	(kg)
V_c =	volume of the cement mixture	(m^3)
ρ_c =	apparent density of the cement mixture	(kg/m^3)

and further

m_i =	mass of a component	(kg)
V_i =	volume of a component	(m^3)
ρ_i =	density of a component	(kg/m^3)
ν_i =	volume fraction of a component ($\nu_i = V_i/V_c$)	

where i denotes p (polymer), m (the part of the monomer that actually polymerizes), *rm (residual monomer)*, ap (additives to the polymer powder), am (additives to the monomer liquid), ac (additives to the cement mixture), po (powder *component), li (liquid component)*

The fraction of the monomer that actually polymerizes in the mixture can be calculated from

$$\nu_m = \frac{\rho_{po}}{\rho_{po} + P/L\times10^3} + \nu_{rm} - \nu_{am} \qquad (5\ 1)$$

The density of the *polymer* is reported as $\rho_p = 1\ 18\times10^3\ kg/m^3$ (Charnley, 1970) and $P/L \approx 2$, if it is assumed that the residual monomer and the additives to the liquid each comprise approximately 3% of the liquid component, it follows that $\nu_{rm} + \nu_{am} \approx 0\ 02$ The monomer fraction ν_m for given P/L ratio can be evaluated from fig 5 1, for which formula (5 1) was used

If a third component (ac) is added to the powder *liquid mixture, the monomer fraction in* the three component mixture can be calculated from

$$\nu_m = \nu'_m (1 - \nu_{ac}) \qquad (5\ 2)$$

where ν'_m denotes the *monomer fraction in the original two component mixture*

This formula (5 2) will be used in chapter [illegible]

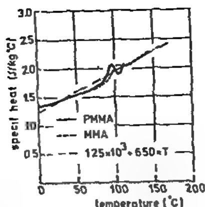

fig 5 3 Temperature-dependent heat capacities of MMA and PMMA, as established by Hoffmann (in Oest et al, 1975) and linear approximation

If $\nu_{ac} = 0$ it follows assuming $C_p \approx C_m$ that

$$C_c \approx C_p + (1 - \nu_m)(C_{ap} - C_p)\frac{\mu}{\rho_{ap}/\rho_p + \mu} \qquad (5\ 6)$$

where

$\mu = m_{ap}/m_p$

If $\nu_{ap} = 0$ it follows that

$$C_c \approx C_p + \nu_{ac}(C_{ac} - C_p) \qquad (5\ 7)$$

Formulas (5 6) and (5 7) will be used in chapter 9

The heat capacity of the cement mixture C_c will, apart from a temperature dependency owing to c_p and c_m, also be affected by dimensional changes, due to the contraction of the monomer during the polymerization process
Taking both effects into account, it follows that

$$C_c(t) \approx \{1\ 25\times10^3 + 6\ 5T(t)\}\{\rho_p + \nu_m(1 - p(t))(\rho_m - \rho_p)\} \qquad (5\ 8)$$

If the cement mixture polymerizes adiabatically (ideally isolated) the temperature T(t) in the mass is described by

$$C_c\frac{dT}{dt} = Q\frac{dp}{dt} \qquad (5\ 9)$$

By calculation of T(t), using the polymer ...
well as for C_c according to f...
two cases results if the (con...
1978) The estimated heat capacity values are summarized in table 5 I

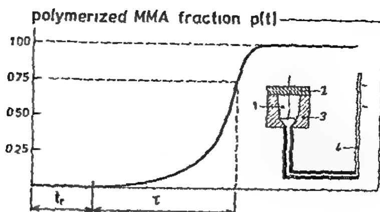

fig 5 2 The polymerization function p(t) as measured by de Wijn (1977) in shrinkage tests using the apparatus shown in the inset, 1 cement mass, 2 Delrin lid, 3 Delrin cup, 4 glass tube filled with liquid to register the amount of shrinkage In dimension less form ($p_1 = p_1(t\ t_r/\tau)$) this curve is assumed to be valid for acrylic cement in general

It should be remarked here that slightly different curves (p_2 and p_3) will also be investigated later

5 3 Heat capacity and conductivity properties

The heat capacity C *(J/m^3°C) of a material can be calculated from* $C = \rho c$, *where* c = *specific* heat (J/kg°C), ρ = density (kg/m^3)
The thermal conductivity of a material is denoted by λ *(J/msec°C) These symbols are* applied with indices, e g c_i, ρ_i, λ_i, where i denotes the material (c (cement mixture), b (bone), *etc*)
In general c, ρ and λ may depend on the temperature and on phase transitions but, as discussed in chapter 4, these dependencies will be neglected in the analyses

5 3 1 *Acrylic cement*

Kaye and Laby (1959) and Debrunner *et al* (1976) give for the specific heat of PMMA $c \approx 1\ 46\text{x}10^3$ J/kg°C Hoffmann (cited by Oest *et al*, 1975) investigated the temperature dependency of c, with respect to PMMA as well as MMA, fig 5 3 shows the results of this study There appears to be little difference in the values for both materials Both curves can be approximated by $c_m \approx c_p \approx 1\ 25\text{x}10^3 + 6\ 50T$ $(0 \lesssim T \lesssim 100)$
Values for the specific heat and the density of radiopaque additives, as given by Muller (1975), are shown in table 5 1

The heat capacity of the cement mixture can be calculated from

$$C_c = \nu_p C_p + \nu_m C_m + \nu_{ap} C_{ap} + \nu_{ac} C_{ac} + \nu_{am} C_{am} + \nu_{rm} C_{rm} \qquad (5\ 5)$$

the last two terms of which may be neglected

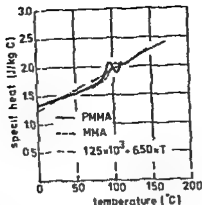

fig 5 3 Temperature-dependent heat capacities of MMA and PMMA, as established by Hoffmann (in Oest et al, 1975) and linear approximation

If $\nu_{ac} = 0$ it follows assuming $C_p \approx C_m$ that

$$C_c \approx C_p + (1 - \nu_m)(C_{ap} - C_p)\frac{\mu}{\rho_{ap}/\rho_p + \mu} \qquad (5\ 6)$$

where

$\mu = m_{ap}/m_p$

If $\nu_{ap} = 0$ it follows that

$$C_c \approx C_p + \nu_{ac}(C_{ac} - C_p) \qquad (5\ 7)$$

Formulas (5 6) and (5 7) will be used in chapter 9

The heat capacity of the cement mixture C_c will apart from a temperature dependency owing to c_p and c_m also be affected by dimensional changes, due to the contraction of the monomer during the polymerization process
Taking both effects into account it follows that

$$C_c(t) \approx \{1\ 25\text{x}10^3 + 6\ 5T(t)\}\{\rho_p + \nu_m(1 - p(t))(\rho_m - \rho_p)\} \qquad (5\ 8)$$

If the cement mixture polymerizes adiabatically (ideally isolated) the temperature T(t) in the mass is described by

$$C_c\frac{dT}{dt} = Q\frac{dp}{dt} \qquad (5\ 9)$$

By calculation of T(t) [illegible]
well as for C_c acc[illegible]
two cases results [illegible]
1978) The estimated heat capacity values are summarized in table 5 1

	density kg/m³	specific heat J/kg°C	heat capacity J/m³°C

HDPE	0 96x10³	2 22x10³	2 06x10⁶	0 29	Kaye and Laby (1959)
Teflon	2 2x10³	1 04x10³	2 29x10⁶	0 23	Kaye and Laby (1959)

table 5 II Thermal properties of some industrial materials

5 3 3 *Bone*

Measurements of thermal properties of various soft tissues in the body have been carried out by several investigators (e g Balasubramanian *et al* 1977) data on bone are scarce however and the values available show a considerable scatter
No doubt the properties greatly depend on the macroscopic structure either trabecular (spongeous) or cortical (compact) the microscopic structure for example orientation and coarseness of the bone matrix the fat content the water content and the macroscopic and microscopic vascularity Hence great individual differences probably occur while properties *in vivo* too may differ from those of cadaveric material
Values for the heat capacity properties as reported in the literature are summarized in table 5 III

or

the rough technique and influences of the sub periosteal vascularity at the outside surface of the bone Altogether it appears that, presently, λ_b for wet cortical bone should be

assumed as approximately 0 4 J/msec°C, for spongeous bone in vivo from 0 36 to 0 60 J/msec°C Since the experiments by Graf and Stein (1957) were carried out in vivo and in vitro in the same kind of bone (sternum) using the same technique, the differences reflect the influence of the vascularity

As regards the influence of the vascularity on the heat conduction properties of the bone structure, three aspects can be distinguished (1) the influence of the microcirculation on the heat conduction properties of the bone material, (2) the influences of large blood vessels and (3) the heat transport at the bone surface in the highly vascularized periosteum As to the first effect, it can probably be assumed that the continuum model of the bone material still applies, but that λ_b should be adapted (Graf and Stein, 1957) The second effect will probably greatly disturb the heat flow, but is a quite local phenomenon that will be neglected here The third effect will be discussed in paragraph 5 4

With regard to long bones it has been shown (Rhinelander, 1972) that the greater part of the cortex thickness (> 2/3) is vascularized from within the medullar system and only the superficial part by the periosteal system In the diaphyseal region, the intramedullar vascularity is, at least temporarily, disturbed prior to fixation of endoprostheses and hence the greater part of the cortex will be without circulation until the periosteal system takes over the function of the intramedullar system (Rhinelander, 1972). It is therefore assumed as probable that the vascularity will exert no influence on the thermal conductivity in the diaphyseal cortex during the polymerization process

As regards the metaphyseal and epiphyseal regions of the bone, where the implant is fixated against spongeous bone, the function of the vascularity during surgery is uncertain, at least part of the circulation will be temporarily disturbed

Possible influences of the microcirculation can be evaluated by variation of λ_b, guided by the results of Graf and Stein (1957), as shown in table 5 IV

5 3 4 *The cement bone interface*

It is a well known phenomenon that when heat flows across a contact region between two materials, the temperatures in the two materials at the contact surfaces are not equal the contact region has a certain heat flow resistance (e g Jacobs and Starr, 1939, Fried, 1969) The heat resistance depends mainly on the roughness of the materials and the kind of intermediate medium (gas, liquid)

This contact heat resistance phenomenon can, in the simplest form, be described by

$$q = \beta \Delta T \qquad (5\ 10)$$

where q is the specific heat flow through the contact region (J/m²sec),
ΔT the temperature drop over the interface (°C),
β the interface conductivity (J/m²sec°C)

This mathematical model is illustrated in fig 5 4 Owing to the (in this case steady) heat flow (q) there is a certain temperature profile in materials 1 and 2 At the contact region or interface which is assumed to be infinitely thin, a discontinuity (ΔT) in the temperature profile is present, due to the heat flow resistance, the conductivity of the interface is described by β In reality, as illustrated in fig 5 4, the interface has a certain thickness (s_i), over which the temperature decreases more-or less continuously

The conductivity of the cement bone interface will depend on the structure and the preparation of the bony implant bed, the consistency of the cement and the pressure applied to it when inserted, the presence of blood, water or bone debris and probably the dimensional behavior of the cement mass Owing to these random influences and the small dimensions,

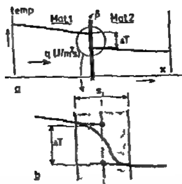

fig 5 4 Illustration of a simplified model of an interface heat resistance (a), showing the temperature profile in the two materials and the discontinuous temperature drop at the interface, assumed as infinitely thin, in reality (b) the interface has a certain thickness and the temperature drop is more-or less continuous

too, the interface conductivity, provided the linear model applies to this complicated structure, will be very difficult to measure Hence the strategy will be to vary the interface conductivity β in a 'possible' range in the analyses and to evaluate its influence on the heat conduction process

In order to obtain a rough impression of the value of β, the steady state heat conduction in a plane model of an arbitrarily shaped bone cement interface was analysed, using the methods described in chapter 4 The model is shown in fig 5 5, the interface is assumed to

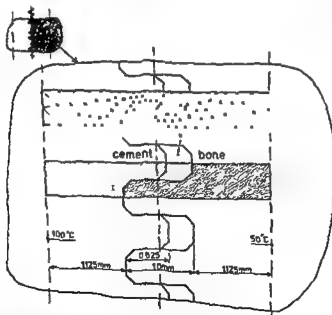

fig 5 5 A simplified plane model of an arbitrary cement-bone interface In the trabecular voids a nonconductive material is assumed, the element mesh for the simulation of the (steady state) heat conduction through the interface is shown

be 1 mm thick and consists of bone 'trabeculae', partly in contact with acrylic cement, leaving intratrabecular gaps filled with a nonconductive medium For reasons of symmetry only a part of the model has to be regarded, the element mesh is shown in fig 5 5 (generat by computer, *Schoofs et al, 1978)* Parameter values were taken as $C_c = 1\ 8\times10^6$ J/m³°C, $C_b = 2\ 9\times10^6$ J/m³°C, $\lambda_c = 0\ 17$ J/msec°C, $\lambda_b = 0\ 4$ J/msec°C Fig 5 6 shows the tempera ture profile on two lines in the materials, as calculated in the computer simulation

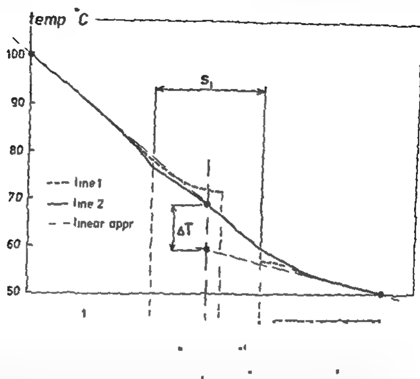

fig 5 6 Temperature profiles in the interface model on two lines as calculated in the FEM simulation and a linear approximation of these profiles in each material, which results in an apparent discontinuous temperature drop ΔT

Linear approximations of the temperature profiles were fitted to these graphs, resulting in a discontinuous temperature drop (ΔT) over an assumed infinitely thin 'interface' located in the middle of the real interface In this simplified description the specific heat flow can be calculated from

$$q = -\lambda_b \frac{dT_b}{dx} = -\lambda_c \frac{dT_c}{dx},$$

where $T_b(x)$ = temperature in bone (linear approximation),
$T_c(x)$ = temperature in cement (linear approximation)

The interface conductivity β can then be calculated from (5 10), which gives $\beta = 375$ J/m²sec°C in this case
Isotherms, as calculated with the FEM model, are shown in fig 5 7, indicating that the tips of the trabeculae, surrounded by cement, will reach high temperatures even if the tempe ratures in the rest of the bone are not very high

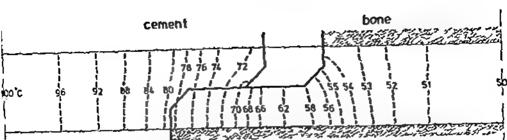

fig 5 7 Isotherms as calculated in the computer simulation indicating that the tips of trabeculae, surrounded by cement, may reach quite high temperature values

At the rather smooth cement implant interface the heat resistance will be low A value of β_{ci} = 1,000-10,000 J/m²sec°C should be appropriate (Fried, 1969)

5 4 Boundary heat transport

Heat loss at the boundary of the model, which will usually be the bone surface, depends on a surface conduction and convection coefficient (α), as discussed in chapter 4, and on the ambient temperature (T_a)
When the bone surface is the boundary of the model the coefficient α depends on the heat exchange mechanism between the superficial bone and the periosteal circulation, although no doubt conduction through the soft tissue also occurs Nothing appears to be known about these phenomena.
For technical surfaces in different media values for α were reported by Grober *et al* (1961), as shown in table 5 V

Medium (free convection)	α (J/m²sec°C)		Medium (forced convection)	α (J/m²sec°C)	
gas	3	24	gas	11	117
water	116	698	viscous liquids	58	582
bubbling water	1,163	23,260	water	581	10,630

table 5 V Values of α with respect to technological surfaces in different media (after Grober et al, 1961)

Blood and soft tissues consist mainly of water and it has been shown that the thermal conductivity of soft tissues is only slightly less than water (water $\lambda \approx 0.6$ J/msec°C (20°C), Eckert and Drake (1972), muscle $\lambda \approx 0.5$ J/msec°C (21°C), Balasubramanian *et al* (1977)) In view of the values given in table 5 V it is then quite probable that $\alpha > 500$ J/m²sec°C and remotely possible that $100 < \alpha < 500$ J/m²sec°C The probability that there is an adequate heat transport at the bone surface was confirmed by d Hollander *et al* (1976), who measured a temperature increase of only 3°C at the outside surface of the femur during hip replacement, the temperature dropped after reaching this peak value

5 5 Initial and ambient temperatures

The temperatures in the components of the bone prosthesis system, prior to insertion of the implant, depend on the circumstances Implants and bone cement will be approximately at 'room temperature' although both components may have been slightly warmed up by manual handling and the onset of the polymerization process The initial temperature of the bone (T_{0b}) is probably equal to the ambient temperature (T_a), which will not be higher than 37°C, but probably somewhat lower, for instance d Hollander *et al* (1976) have measured values between 32 and 35°C (see paragraph 2 1)

5 6 Conclusions

Based on a thorough review of the relevant literature, estimates for the thermal properties of bone prosthesis systems have been discussed in this chapter
The geometry of the system has not been discussed, as it depends so much on the joint component which is under consideration and can better be treated in the chapters concerned
A summary of probable and possible values is shown in table 5 VI It should be borne in mind that in some cases the values and value ranges shown are only educated guesses, especially where the 'possible range' is concerned Sometimes (as for example for λ_c) only one value is shown in the 'probable value or range' column simple because only one value has been published, the 'possible range' column then reflects uncertainty about this value The ranges in these columns will be used later as lower and upper boundaries in the parametric analyses Some parameters are adjustable, for instance ν_m (by the P/L ratio) and C_c (by additives), the probable ranges of adjustability are then shown in the relevant column

As can be concluded from table 5 VI many properties might well come in for more thorough experimental investigations For such investigations it is of importance to know how sensitive the process of heat generation and conduction is for the parameter values, so as to establish which parameters are the most important and the accuracy with which each parameter would have to be measured Analyses such as those presented in the following chapters where the influences of the parameters on the process are evaluated, can provide guidelines for such experiments

CHAPTER SIX

EVALUATION OF THE MODEL

In order to evaluate the model as to its suitability for the curing cement and judge the parameter value estimates, two experiments published in the literature were simulated As not all the parameters that have to be given a value in the model calculations were measured in the experiments and the reliability of the experimental results is sometimes doubtful, this simulation process cannot be regarded as a true verification procedure, but merely as a rough evaluation

6.1 A ball of curing acrylic cement

Ohnsorge and Kroesen (1969) measured temperatures as a function of time in the centre and at the surface of a ball of acrylic cement curing in free air Parameter-values that can be derived from their publication are given in table 6 I

commercial brand	Palacos	initial temperature	T_{0c} = 25°C
P/L ratio	2 1 gr/cc	ball radius	R = 2 2x10^{2} m
ambient temperature	T_a = 25°C	ball mass	m_c = 52 2x10^{3} kg

table 6 I Data from Ohnsorge and Kroesen (1969)

The monomer fraction in the mixture can be evaluated using fig 5 1 and the given P/L ratio, from which it follows that $\nu_m \approx 0\ 34$ Hence, using the data presented in paragraph 5 2, $Q \approx 1\ 7 \times 10^{8}$ J/m³ For cooling in free air, $\alpha \approx 3$ 24 J/m² sec°C (table 5 V)
Owing to symmetry of the ball, only a section has to be taken into account in the analysis Fig 6 1 shows the element mesh for the axisymmetric model At the boundaries $r = 0$ and $z = 0$, α is taken as zero to simulate the spherical geometry Of course, a spherical model would be more appropriate here from a theoretical point of view, however, the computer program is only suited for plane and cylindrical models
The time step Δt in the solution procedure was taken as 10 sec, 100 steps were taken into account The polymerization function $p_1(t)$ was used, with $t_r = 0$ and $\tau = 240$ sec (a value that will be motivated at the end of this paragraph)
Fig 6 2 shows an example of calculated results the temperature in the ball as a function of r, for three different values of α, at time t = 350 sec It is found even for rather high values of α, that the heat flow from the centre (which is proportional to $\frac{dT}{dr}$) is practically zero Hence the process in the centre is practically adiabatic Since in that case (near the centre)

$$C_c \frac{dT}{dt} = Q \frac{dp}{dt}, \text{ hence } T(t) = \frac{Q}{C_c} p + T_{0c},$$

it follows that

fig 6 1 ... lat on of the heat generation and conduction

CHAPTER SIX

EVALUATION OF THE MODEL

In order to evaluate the model as to its suitability for the curing cement and judge the parameter value estimates, two experiments published in the literature were simulated As not all the parameters that have to be given a value in the model calculations were measured in the experiments and the reliability of the experimental results is sometimes doubtful, this simulation process cannot be regarded as a true verification procedure, but merely as a rough evaluation

6 1. A ball of curing acrylic cement

Ohnsorge and Kroesen (1969) measured temperatures as a function of time in the centre and at the surface of a ball of acrylic cement curing in free air Parameter values that can be derived from their publication are given in table 6 I

commercial brand	Palacos	initial temperature	T_{0c} = 25°C
P/L ratio	2 1 gr/cc	ball radius	R = 2 2x10^{-2} m
ambient temperature	T_a = 25°C	ball mass	m_c = 52 2x10^{-3} kg

table 6 I Data from Ohnsorge and Kroesen (1969)

The monomer fraction in the mixture can be evaluated using fig 5 1 and the given P/L ratio, from which it follows that $\nu_m \approx 0\ 34$ Hence, using the data presented in paragraph 5 2, $Q \approx 1\ 7\times10^8$ J/m^3 For cooling in free air, $\alpha \approx 3$ 24 J/m^{2}sec°C (table 5 V)
Owing to symmetry of the ball, only a section has to be taken into account in the analysis Fig 6 1 shows the element mesh for the axisymmetric model At the boundaries r = 0 and z = 0, α is taken as zero to simulate the spherical geometry Of course, a spherical model would be more appropriate here from a theoretical point of view, however, the computer program is only suited for plane and cylindrical models
The time step Δt in the solution procedure was taken as 10 sec, 100 steps were taken into account The polymerization function $p_1(t)$ was used, with $t_r = 0$ and $\tau =$ 240 sec (a value that will be motivated at the end of this paragraph)
Fig 6 2 shows an example of calculated results the temperature in the ball as a function of r, for three different values of α at time t = 350 sec It is found even for rather high values of α, that the heat flow from the centre (which is proportional to $\frac{dT}{dr}$) is practically zero Hence the process in the centre is practically adiabatic Since in that case (near the centre)

$$C_c \frac{dT}{dt} = Q \frac{dp}{dt}, \text{ hence } T(t) = \frac{Q}{C_c} p + T_{0c},$$

it follows that

6 2. Acrylic cement curing in a Teflon cup

Meyer *et al* (1973) measured temperatures as a function of time at eight locations in acrylic cement, curing in a Teflon cup The cup (and the cement slice) were axisymmetric Initial temperatures, height of the cement slice and P/L ratio were varied The cup is shown together with the element mesh for the simulation in fig 6 4 Only the experiments entailing a cement slice height of 10 mm were simulated Measuring points were numbered 1, 3, 5 and 7 (in the middle of the cement slice) and 2, 4, 6 and 8 (near to the Teflon), all located in an axial section

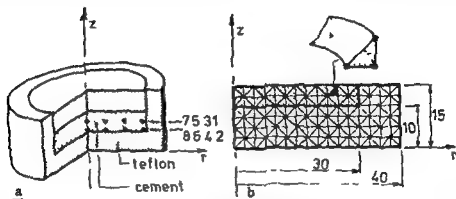

fig 6 4 (a) The Teflon cup with the cement mass as used for experiments by Meyer et al (1973), temperature measuring points are shown, 7 and 8 on the symmetry axis, 7, 5, 3 and 1 in the middle of the mass, 8, 6, 4 and 2 near the Teflon (b) Dimensions and element mesh for the computer simulation

commercial brand	Simplex p
P/L ratio	1 5, 2, 2 5 and 3 gr/cc (ν_m 0 42, 0 35 0 30 and 0 27, fig 5 1)
initial temperature	4, 15, 20, 30 and 37°C
ambient temperature	equal to initial temperature
retardation time	$t_r \approx 150$ sec

table 6 II Data supplied by Meyer et al (1973)

Table 6 II shows some values for parameters that can be derived from the publications of Meyer *et al* Parameter values for Teflon were taken in accordance with table 5 II The polymerization time was chosen in such a way that the time at which the center point temperature (point 7) reached its peak coincided in simulation and experiment (τ = 350 sec for P/L = 2 gr/cc and $T_a = T_{0c} = 25$°C), the poly...

solution procedure the time step (Δt) w...

account, a time step of 1 sec with 1000...

(Huiskes 1977) Values for cement par...

- the temperature in the centre is proportional to the polymerization function, which gi[ves] the option of evaluating this function by measuring the temperature in a comparable experimental set up,
- when the maximal temperature in the centre is denoted by T_c, then

$$T_c - T_{0c} = \frac{Q}{C_c}$$

thus the value of $\frac{Q}{C_c}$ can be evaluated directly from the experiment

For the experiment it was reported that $T_c = 122°C$, hence $\frac{Q}{C_c} = 97°C$

Assuming $Q = 1.7 \times 10^8$ J/m³, it follows that $C_c = 1.75 \times 10^6$ J/m³°C, which is somewhat lower than estimated in chapter 5, but quite realistic The difference could easily be explained by experimental inaccuracies, incomplete polymerization or a slightly different P/L ratio

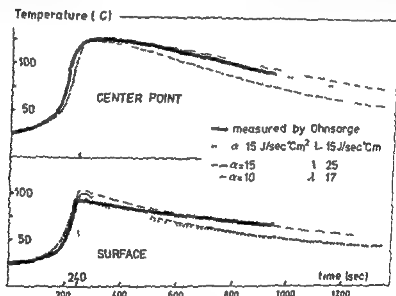

fig 6 3 Temperatures as a function of time in the centre and at the surface of the ball, as measured and as calculated using different values for α and λ

Fig 6 3 shows the centre and surface temperatures as a function of time as calculated for different values of λ and α, compared to the experimental results Obviously the value of λ exerts more influence on the centre temperature, while α exerts more influence on the surface temperature The curve for $\lambda = 0.17$ J/msec°C and $\alpha = 10$ J/m²sec°C shows the best agreement with the experimental curves

The polymerization time τ was chosen in such a way that the time at which the surface temperature reached its peak in the model coincided with the experimental finding

It is remarkable that in using the polymerization function $p_1(t)$ both experimental curves are approximated reasonably well This gives confidence in the applicability of the general shape of this polymerization function

In the experiment the surface temperature was slightly higher than in the simulation

This is probably caused by monomer evaporation at the surface

It should be remarked that, due to the steep temperature gradient, the temperature measurements at the interface are somewhat unreliable Moreover, the exact position of the interface thermocouples is not mentioned in the publication

Fig. 6 6 shows a comparison of temperatures as a function of time as measured and as calculated, where $\beta = 50$ J/m² sec°C, at four of the measuring points Since the location of measuring points 1, 2 and [illegible] is not exactly known, calculated results for points in the neighborhood are shown in the graphs Results of measuring points 3 and 5 were practically equal to those of point 7 and those of points 4 and 6 were practically equal to those of point 8

Again the use of the polymerization function $p_1(t)$ results in quite reasonable approximations of the experimental curves, except for a small shift in the polymerization time at the 'cooler points'

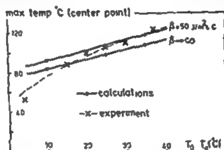

fig 6 7 Maximal cement temperature as a function of the initial temperatures as measured by Meyer et al (1973) and as calculated in the model

Fig. 6 7 shows the influence of the initial temperature on the maximal temperature value in the center point as calculated and as measured Evidently a reliable prediction results from the model so long as the range of variation is not too extended In the experiment an increase in the polymerization time results for low values of T_{0c}, not taken into account in the model

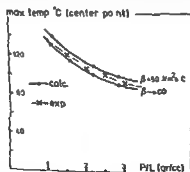

fig 6 8 The maximal cement temperature as a function of the P/L ratio as measured by Meyer et al (1973) and as calculated in the model

Fig. 6.8 shows the influence of the P/L ratio on the maximal temperature value at the center point as calculated and as measured Again, it is apparently possible, using the model, to predict this influence with quite good accuracy

It was established that a variation of α in the range from zero to infinite exerted no significant influence on the maximal cement temperatures Likewise a variation of the Teflon properties within a realistic range, and a variation of λ_c within a realistic range exerted little influence

To be able to obtain a reasonable approximation of the temperatures in all measured points the conductivity at the cement Teflon interface had to be taken as $\beta = 50$ J/m²sec°C

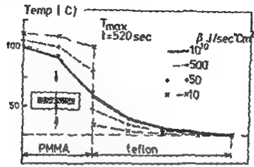

fig 6 5 Temperatures as a function of the axial coordinate (z) in the cement and in the Teflon, at time t = 520 sec, as calculated for different values of the interface conductivity β

Fig 6 5 shows the influence of β on the temperature profiles in cement and Teflon along the axis of the structure The fact that such a rather low value of β has to be assumed to approximate the temperature values measured close to the cement Teflon interface, is probably caused by steep temperature gradients in reality near the interface which cannot be simulated due to the coarseness of the element mesh

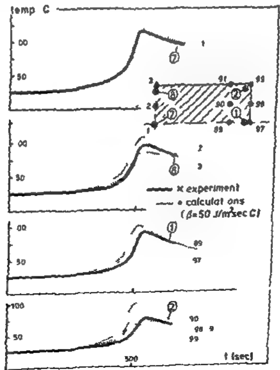

fig 6.6 Temperatures as a function of time, as measured at 4 points in the cement mass by Meyer et al (1973), and as calculated at different points close to the measuring points indicated in the figure

It should be remarked that, due to the steep temperature gradient, the temperature measurements at the interface are somewhat unreliable. Moreover, the exact position of the interface thermocouples is not mentioned in the publication.
Fig. 6.6 shows a comparison of temperatures as a function of time as measured and as calculated, where $\beta = 50\ J/m^2 sec°C$, at four of the measuring points. Since the location of measuring points 1, 2 and 8 is not exactly known, calculated results for points in the neighborhood are shown in the graphs. Results of measuring points 3 and 5 were practically equal to those of point 7 and those of points 4 and 6 were practically equal to those of point 8.
Again the use of the polymerization function $p_1(t)$ results in quite reasonable approximations of the experimental curves, except for a small shift in the polymerization time at the 'cooler points'.

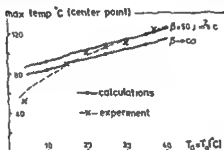

fig. 6.7 Maximal cement temperature as a function of the initial temperatures as measured by Meyer et al (1973) and as calculated in the model

Fig. 6.7 shows the influence of the initial temperature on the maximal temperature value at the center point, as calculated and as measured. Evidently a reliable prediction results from the model so long as the range of variation is not too extended. In the experiment an increase in the polymerization time results for low values of T_{0c}, not taken into account in the model.

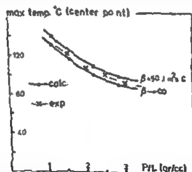

fig. 6.8 The maximal cement temperature as a function of the P/L ratio as measured by Meyer et al (1973) and as calculated in the model

Fig. 6.8 shows the influence of the P/L ratio on the maximal temperature value at the center point, as calculated and as measured. Again, it is apparently possible, using the model, to predict this influence with quite good accuracy.

6.3 Conclusions

By simulation of two experiments presented in the literature it was shown that the process of heat generation and conduction in curing acrylic cement can be simulated with acceptable accuracy and that the estimates for (cement) parameter values discussed in chapter 5 are quite reasonable. The general shape of the measured polymerization function is found to be realistic. Although the polymerization function is not independent of the temperature, it is found that in reality its influence only results in a relatively small shift of the curves, especially in the initial part of the polymerization process. The value of β exerts a considerable influence on temperature values near the interface of the cement and the adjoining material. In the bone prosthesis system this is precisely the location where the temperature values are of interest. As has been discussed previously, results of temperature measurements in this region are unreliable. But, due to the fact that so little is known about the value of β the same is true for calculated temperature values in this region. By conducting parametric analyses, however, a good impression can be obtained on the possible temperature values and the influences of the important parameters on these values. In this respect the model gives much more information than experiments possibly could.

CHAPTER SEVEN

PARAMETRIC ANALYSES WITH RESPECT TO INTRAMEDULLARY FIXATED IMPLANTS

7 1 Description of the model

In this chapter the influences of the relevant parameters on the process of heat generation and conduction in a realistic system will be evaluated by means of parametric analyses In order to maintain insight into the effect of parametric changes, the system to be analysed should be as simple as possible Therefore a both simple and realistic model was chosen

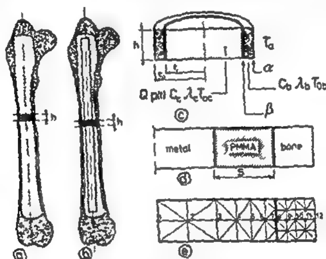

fig 7 1 An arbitrary long bone filled with acrylic cement (a), which may also contain an implant (stem) (b) The axisymmetric model of the diaphysis region is shown (c) giving the parameters that influence the heat generation and conduction process also The dimension of the implant may vary (d), the cement layer thickness is denoted by s The element mesh used in the computer simulation is also shown (e)

The model [illegible] to be zero The model and the model parameters, in the event that no stem is present, are shown in fig 7 1 c When a stem is present, the cement layer thickness is denoted by s (mm) (fig 7 1 d) The element mesh for the model is shown in fig 7 1 e, mesh refinement is applied close to the cement bone interface so as to be able to describe a steep temperature gradient in this region adequately

The parameters were varied with respect to a reference value The set of reference values is shown in table 7 1 In the reference case no implant is present as it will no doubt be the

parameter	unit	reference value	parameter	unit	reference value
Geometry (no implant present)			**Cement**		
r_u	m	16×10^{3}	C_c	J/m³°C	$1\ 75 \times 10^{6}$
r_i	m	12×10^{3}	λ_c	J/msec°C	0 17
s (1)	m	12×10^{3}	T_{0c}	°C	20
Heat-generation			**Bone (cortical)**		
Q	J/m³	$1\ 7 \times 10^{8}$	C_b	J/m³°C	$2\ 9 \times 10^{6}$
p(t)	—	$p_I(t)$	λ_b	J/msec°C	0 4
t_r	sec	0	T_{0b}	°C	37
τ	sec	350			
Cement bone interface			**Bone surface**		
β_{cb}	J/m² sec°C	1,000	α	J/m² sec°C	500
			T_a	°C	37

table 7 I Reference values for parameters in the diaphysis model, (1) In the reference case no implant is present, hence $s = r_i$

'worst case for the bone temperature values The reference values were chosen as more or less probable average values, as summarized in table 5 VI, if there were serious uncertainty about a parameter (as, for instance in the case of β), a more or less 'worst case' value was chosen In table 5 VI, $Q = 1\ 8 \times 10^{8}$ J/m³ and $C_c = 1\ 9 \times 10^{6}$ J/m³°C were given as probable values Based on the results of the simulations described in the previous chapter, $Q = 1\ 7 \times 10^{8}$ J/m³ and $C_c = 1\ 75 \times 10^{6}$ J/m³°C have been chosen as probable values in the forthcoming analyses

For the calculations where a (metal) implant is assumed to be present, values for the para meters are taken in accordance with table 5 II (Cr Ni steel, $C_i = 3\ 6 \times 10^{6}$ J/m³°C, $\lambda_i = 14$ J/msec°C)

Parameters will be varied in what is expected to be a realistic range, which is determined either by uncertainty about the parameter value (see table 5 VI), or by a range in which the parameter may vary in reality, due to circumstances or cement composition Since the solu tion procedure is numerical the parametric analysis is carried out by calculating for each parameter separately the temperatures for several values and interpolating between separate results In some calculations, values different than those shown in table 7 I were taken for other than the varied parameter, where this is the case, the deviating value will be mentioned

Fig. 7 2 a shows temperatures as a function of time in the cement and the bone and fig 7 2 b temperatures as a function of the radius r at three different times The middle of the cement mass (point 1) reaches approximately 121°C (T_c) the bone at the bone cement interface approximately 59°C (T_b)

... the temperature ...

have to be compared to the threshold levels shown ...

To simplify this procedure, the penetration depths of the 50°C and 55°C isotherms into the bone as function of time ($\delta(t)$) were calculated (fig 7 3) The maximal penetration depth of the 50°C isotherm is denoted as δ_m

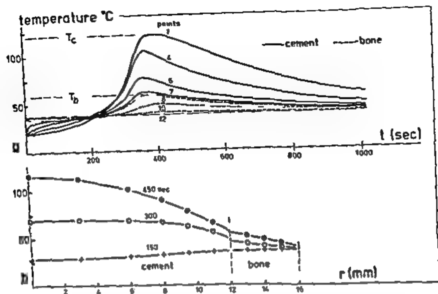

fig 7 2 (a) Temperatures as a function of time at the 12 points indicated in fig 7.1 e, T_c and T_b are the maximal temperatures in cement and bone respectively (b) Temperatures as a function of the radius r at three different times (both calculations of the reference case)

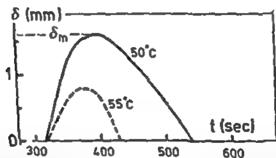

fig 7 3 The penetration depths of the 50°C and the 55°C isotherms into the bone cortex as functions of time, δ_m is the maximal penetration depth of the 50°C isotherm

If this graph is compared to fig 3 1 it is found that about 0 5 mm of the bone would be liable to bone cell necrosis and about 1 mm to vascular damage

To evaluate the influences of parametric changes, three variables that are representative of the temperature distribution will be regarded the maximal cement temperature (T_c as shown in fig. 7 2 a or ΔT_c, defined as T_c -20°C), the maximal bone temperature at the interface (T_b (fig 7 2.a) or ΔT_b, defined as T_b -37°C) and the maximal penetration depth of the 50°C isotherm (δ_m fig 7 3)

7 2 Heat transport at the bone surface

The heat loss at the outside surface of the bone depends on α (J/m²sec°C) and T_a (°C) Theoretically speaking α may vary between zero (bone surface temperature equal to T_a) and infinite (bone completely isolated) Temperatures at the cement and bone points as a function of time for both these upper and lower boundary values are shown in fig 7 4 *In the event of complete isolation the whole system warms up to around 73°C a value that* can easily be verified using data for total heat generation and heat capacity properties

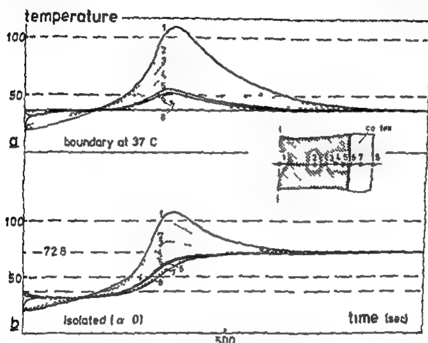

fig 7 4 Temperatures as a function of time at 8 points in the cement and the bone as calculated in the event of an idealized heat transport (a) and of an idealized isolation at the bone surface (b)

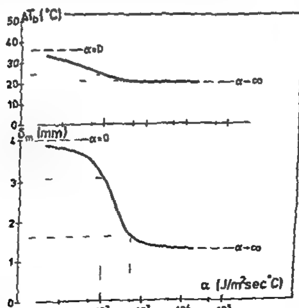

fig 7 5 The influence of α on the maximal bone temperature increase ΔT_b and on the maximal penetration depth of the 50°C isotherm δ_m (logarithmic scale for α)

As follows from fig 7 4 the value of α has no significant influence on T_c The influence of α on ΔT_b is shown in fig 7 5 It is found that α has little influence when $\alpha > 100$ The influence of α on δ_m, too, is shown in fig 7 5, for α to have little influence in this case it would have to be over 500, for [illegible] < 500 the influence is pronounced

7 3 Cement-bone interface conductivity

The influence of β (J/m² sec°C) on ΔT_b and δ_m is shown in fig 7 6, β has a marked influence for $\beta < 1000$ A value of 1000, as used in the reference case, or higher, more-or-less simulates 'worst case' conditions for the bone

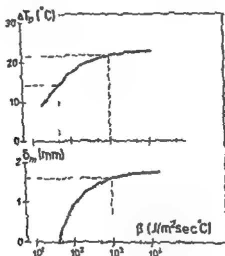

fig 7 6 The influence of β on ΔT_b and on δ_m (logarithmic scale for β)

7 4 Bone and implant dimensions

When a metal implant is present in the cement, it functions [illegible] a 'heat sink', due to its superior heat capacity and conductivity properties An example of temperature values as calculated, assuming an axisymmetric stem of 12 mm thickness in the cement, is shown in fig 7 7 Values taken for the parameters in this case were equal to those in the reference case with the [illegible] en as [illegible] aches [illegible] 1 3 mm [illegible] than 50 [illegible] enough t[illegible] perature [illegible] stem takes up the heat initially and later returns [illegible] to the rest of the system In a real prosthesis stem heat will also flow in the axial direction, which will reduce the temperatures even further

7 2 *Heat transport at the bone surface*

The heat loss at the outside surface of the bone depends on α (J/m² sec°C) and T_a (°C) Theoretically speaking, α may vary between zero (bone surface temperature equal to T_a) and infinite (bone completely isolated) Temperatures at the cement and bone points as a function of time for both these upper and lower boundary values are shown in fig 7 4 In the event of complete isolation, the whole system warms up to around 73°C, a value that can easily be verified using data for total heat generation and heat capacity properties

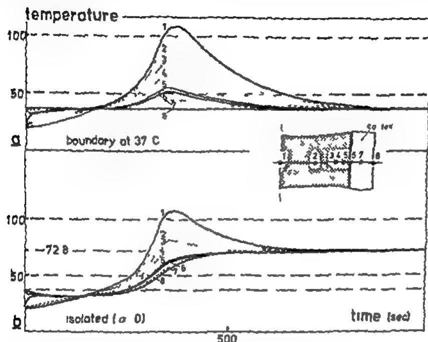

fig 7 4 Temperatures as a function of time at 8 points in the cement and the bone as calculated in the event of an idealized heat transport (a) and of an idealized isolation at the bone surface (b)

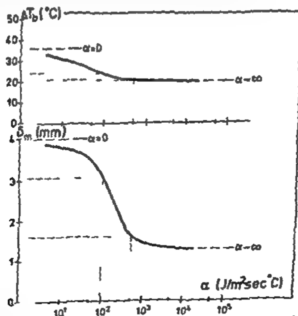

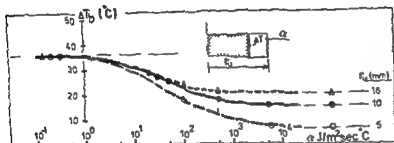

fig 7 5 The influence of α on the maximal bone temperature increase ΔT_b and on the maximal penetration depth of the 50°C isotherm δ_m (logarithmic scale for α)

	r_i (mm)	r_u (mm)	simulated bone
... on	12	16	human femur
...iation 1	7 5	10	dog femur
...ariation 2	3 75	5	rabbit femur

7 II Variations in bone dimension

g 7 8 The influence of α on ΔT_b for three different bone dimensions (logarithmic scale for α)

α ≈ 100 the difference between the dog bone and the human bone will have practically anished and for α ≈ 10 the difference between the rabbit bone and the human bone As previously probably $\alpha > 500$ hence results of animal experiments in this respect simply be translated into human circumstances

/hen animals have to be used as models in this respect, a method of scaling could be intro When the differential equation that describes the process of heat generation and (chapter 4) is written in dimensionless form it follows that if the dimensionless mbers

$\frac{\lambda_c}{r_i^2}$ and $\frac{\tau\lambda_b}{C_b(r_u-r_i)^2}$ (Fourier number)

$\frac{\beta(r_u\ r_i)}{\lambda_b}$ and $\frac{\alpha(r_u-r_i)}{\lambda_b}$ (Biot number)

$\frac{Q}{T_a}$ and r_u/r_i

equal in the human and the animal model the results will be equal in both cases. For the ourier numbers this could be accomplished by adapting the polymerization time (τ) and heat capacity of the cement (C_c) in the animal case, then also Q would have to be for the source number (Q/C_cT_a)

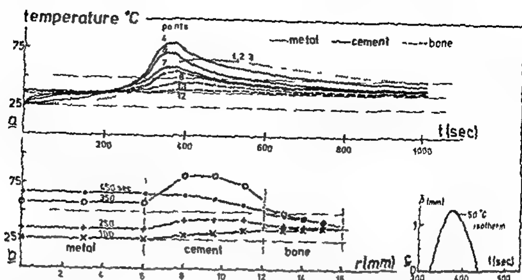

fig 7 7 (a) Temperatures as a function of time in implant, cement and bone, at 12 points (indicated in fig 7 1 e), (b) temperatures as function of the radius r in the three materials at three different times, (c) penetration depth of the 50°C isotherm into the bone cortex as function of time.

By varying the bone dimensions, the influence of individual differences can be evaluated, and the possibilities can be judged of using animal models in experimental heat-conduction studies in vivo

In first order approximation, the relation between heat generation and heat conduction in a system can be estimated by comparing the heat producing volume to the heat-transporting surface In the medullary canal, assuming axisymmetry, the ratio between these two para meters (volume/surface) is proportional to the inner bone radius r_i Hence it should be expected that the temperature values measured in bones of small animals are not represen [illegible] regarding [illegible]

which is found from (e g Eckert and Drake, 1972)

$$R_c = \frac{ln(r_u/r_i)}{\lambda_b} + \frac{1}{\alpha r_u} \qquad (7\ 1)$$

From (7 1) it follows that α exerts its greatest influence on the smaller bone When $\alpha \rightarrow \infty$, R_c depends on $ln(r_u/r_i)/\lambda_b$ only and if r_u/r_i and λ_b were constant in different animals, deviations in the bone temperatures would be due to differences in the heat generation conduction relation only When $\alpha = 0$, the heat resistance is infinite and in this case the end temperature of the system depends on the total heat generation in the cement and the heat capacity of the cement and the bone, hence on the ratio volume cement/volume cement-and bone, in the event that r_u/r_i is constant in different animals this ratio, and hence the maximal temperature, is equal

To investigate the differences further, the model was analyzed for different dimensions (see table 7 II), in all three cases $r_u/r_i = 1\ 33$ was assumed

Fig 7 8 shows the influence of α on the maximal bone temperature increase ΔT_b for the three different dimensions As was previously predicted, for low α and for high values of α it has no influence on the differences in ΔT_b, while for low values there is no difference

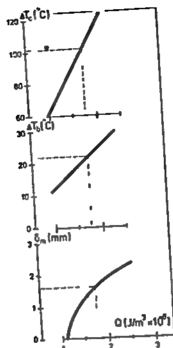

fig 7.10 The influence of Q on ΔT_c, ΔT_b and δ_m

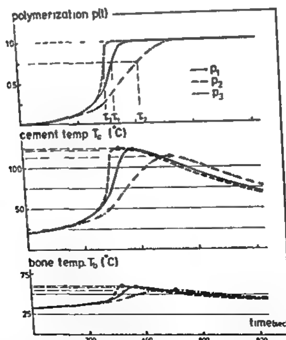

fig 7.11 From top downwards the three polymerization functions applied ($p_1(t)$, $p_2(t)$, $p_3(t)$), the cement temperature (center point) and the bone temperature (interface) that result from these functions

Little can be done to satisfy the requirements for the Biot numbers, so scaling would only be possible if $\alpha \rightarrow \infty$ and $\beta \rightarrow \infty$

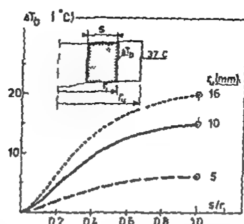

fig 7 9 Maximal bone temperature increase (ΔT_b) as a function of the relative cement layer thickness (s/r_i), for three different bone dimensions (r_u/r_i constant)

Fig 7 9 shows the maximal temperature increase of the bone (ΔT_b) in the event that an implant is present as a function of the ratio between the thickness of the cement layer and the inner radius of the bone (s/r_i), for the three bone dimensions In the calculations on which these results are based, α was taken as infinite For $s/r_i = 1$, no implant is present in the cement and the medullary canal is completely filled with acrylic cement As follows from these graphs, besides the bone dimension the thickness of the cement layer (the thickness of the implant) has a marked influence on the maximal bone temperature

As to influences of individual differences in bone dimension, these can also be estimated using formula (7 1) When the differences are such that r_u/r_i remains constant the previously discussed influences apply in the same way
When the cortex thickness varies, assuming equal r_i, only the heat conduction properties change It can be calculated from formula (7 1) that, with respect to the (human) reference case ($\alpha = 500$ J/m²sec°C), a variation in cortex thickness from 3 to 5 mm has the same influence as a variation in α from about 3250 to 222 J/m²sec°C, a variation that hardly affects ΔT_b but has a significant influence on δ_m (fig 7 5)

7 5 Heat generation parameters

The heat generation in the cement depends on Q and on p(t) The influence of Q on ΔT_c, ΔT_b and δ_m is shown in fig 7 10 Q has a marked influence on all temperature values

Apart from the polymerization function $p_1(t)$ two other curves were applied, $p_2(t)$, a slower curve and $p_3(t)$, a faster curve, respectively (fig 7 11) These curves were different especially in their auto acceleration aspect, the best way to characterize these differences ... polymerization rate ($\theta_p = \max(dp/dt)$) rather then by their polymeri...) ^{3}sec^{-1}, $\theta_{p3} = 28 \times 10^{-3}$sec^{-1}) The resulting ... time for these three curves are shown in fig 7 11

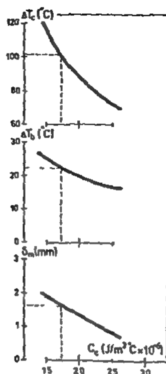

fig 7.13 The influence of C_c on ΔT_c, ΔT_b and δ_m

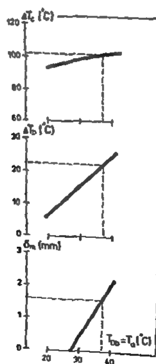

fig 7.14 The influence of $T_{0b} = T_a$ on ΔT_c, ΔT_b and δ_m

The results for curve $p_3(t)$ are practically equal to those of an idealized 'snap curing' ce which is as fast as possible Application of curve $p_2(t)$ gives a reduction of about 4°C in maximal interface bone temperature T_b as compared to curve $p_1(t)$, and a reduction of about 0 5 mm in δ_m Between the results of curves $p_1(t)$ and $p_3(t)$ there is only a slight difference

7 6 Heat capacity and conductivity parameters

The influence of the heat capacity of the bone is but slight over a wide range For $2x10^6 \leq C_b \leq 4x10^6$ J/m³°C, the influence on T_c is insignificant, T_b varies betwee 60°C and 57°C and δ_m varies between 1 8 mm and 1 3 mm

The conductivity of the bone, λ_b, has a greater influence on both T_b and δ_m especially low values Fig 7 12 shows the influence on ΔT_b, for $0\,2 \leq \lambda_b \leq 2\,0$ J/msec°C and different values for α It should be remarked that such a wide range for λ_b is not realisti

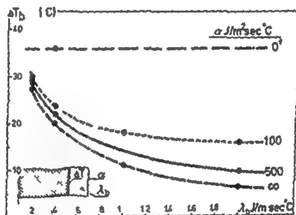

fig 7 12 The maximal bone temperature increase (ΔT_b) as a function of λ_b, for different values of α

The value of λ_c has no significant influence on T_c For $0\,14 \leq \lambda_c \leq 0\,20$ J/msec°C, which is a rather wide range, T_b varies between 57°C and 60°C, and δ_m varies between 1 3 mm and 1 7 mm
The heat capacity of the cement, C_c, has a marked influence on T_c T_b and δ_m in a range of $1\,5x10^6 \leq C_c \leq 2\,5x10^6$ J/m³°C, as is shown in fig 7 13 C_c is one of the parameters that can be adjusted by adding material of a higher heat capacity to the cement, as will be discussed in chapter 9

7 7 Initial and ambient temperatures

The influence of the cement initial temperature on T_c, T_b and δ_m in a range of $15 < T_0 < 25$°C is quite insignificant A greater range is not realistic at least not in the affect the polymerization

... factor would in first order approximation

Both T_b and δ_m are greatly influenced by the initial bone temperature T_{0b} and the ambient (periosteal blood) temperature T_a, as shown in fig 7 14 T_{0b} and T_a are taken as equal, because both represent the local temperature of the biological system

The *implant initial temperature, in the event that an implant is present*, was not varied As follows from a first order approximative consideration of the 'heat sink' capacity of the implant, reducing the initial temperature by 10°C will have about the same influence as increasing the stem radius by 1 mm (for a radius of approximately 6 mm)

7 8 Conclusions

The *influence of* α ($J/m^2 sec°C$) on the temperature values is slight if $\alpha > 500$ If $\alpha < 500$, however, the influence especially on δ_m is quite pronounced, a lower value of α would then make a greater part of the cortex liable to necrosis As discussed in paragraph 5 4 it is quite probable that $\alpha > 500$
The influence of the *interface conductivity is pronounced if* $\beta < 1000$ $J/m^2 sec°C$ This might well be so and in that case the temperatures in the bone may be much lower, although it should be borne in mind that in single trabeculae surrounded by cement the bone may still reach high maximal temperature values, as discussed in paragraph 5 3 4
The influence of the polymerization curve p(t) on T_c and T_b is not very outspoken in a realistic range of polymerization rates If the 'Trommsdorf effect' (the auto acceleration phase of the process) were significantly surpressed, as in curve no 2, some temperature reduction would be evident, but probably less than sometimes expected (de Wijn, 1974, Huiskes *et al*, 1977) The reduction of the penetration depth δ_m, however, is quite pronounced for a slow curve
Also the presence of a metal stem in the cement (as, for instance in intramedullary fixated implants) has a marked effect on the temperatures The influence of the stem thickness is great, owing to a combined effect of a greater 'heat sink' capacity of the implant and a lesser cement layer thickness

The influences of the other parameters on T_c, T_b and δ_m can be linearized in the neighbourhood (usually over a fairly wide range) of their reference values
The linearized influences are summarized in table 7 III as percentage increase in T_c, T_b and δ_m per percentage increase in the parameter value
It is remarkable that Q, C_c and $T_{0b} = T_a$ exert the greatest influences These parameters belong to the ones that can be influenced by the surgeon or the cement manufacturer, as will be discussed in chapter 9

It was shown in the reference calculation that the bone reached a maximal temperature of approximately 59°C, while the inner cortex up to 1 6 mm from the interface reached temperature of 50°C and over Where there was a (metal) implant of 12 mm in thickness the bone reached a maximal temperature of 54°C, while 1 3 mm of the inner cortex reached a temperature of 50°C or over As these temperatures were maintained for only a short time, the cortex tissue in the latter case would not be liable to tissue necrosis, applying the threshold curve of fig 3 1
Due to uncertainties in the parameter values, these quantities should not be regarded in too absolute a sense A valid impression of the influences exerted by the probable and possible ranges of parameter values on the bone temperature rise (ΔT_b) and the penetration depth (δ_m) is given by the diagram in fig 7 15 The ranges for the parameters are shown in table 7 IV as

It is remarkable that Q, C_c and $T_{0b} = T_a$ exert the greatest influences These parameters belong to the ones that can be influenced by the surgeon or the cement manufacturer as will be discussed in chapter 8

It was shown in the reference calculation that the bone reached a maximal temperature of approximately 59°C, while the inner cortex up to 1 6 mm from the interface reached temperature of 50°C and over Where there was a (metal) implant of 12 mm in thickness the bone reached a maximal temperature of 54°C, while 1 3 mm of the inner cortex reached a temperature of 50°C or over As these temperatures were maintained for only a short time, the cortex tissue in the latter case would not be liable to tissue necrosis, applying the threshold curve of fig 3 1

Due to uncertainties in the parameter values, these quantities should not be regarded in too absolute a sense A valid impression of the influences exerted by the probable and possible ranges of parameter values on the bone temperature rise (ΔT_b) and the penetration depth (δ_m) is given by the diagram in fig 7 15 The ranges for the parameters are shown in table 7 IV as

cortex in a very small zone near the interface is just possible If the influence of the initial bone temperature, probably less than 37°C, is taken into account, necrosis would be improbable. Also, it can be concluded that, in the case of the rabbit femur, where the whole medullar canal is filled with acrylic cement, tissue necrosis is quite improbable. One should be cautious with such conclusions in an analysis of this kind that is in essence meant to evaluate influences and tendencies rather than to find absolute data. However, it appears very unlikely that the bone tissue necrosis found by Feith (1975) in his rabbit experiments would be principally caused by the heat of polymerizing, as will be further discussed in paragraph 7.9

At this point it should be remarked that although the thermal damage threshold curves in fig 3 1 were introduced as convenient criteria for judging the possibilities for thermal damage [illegible]

necrosis within a region of 0 - 1.5 mm of the cortex is a distinct possibility. In the case of the rabbit femur necrosis would still be improbable

However uncertain these conclusions are in an absolute sense, it is clear that bone prosthesis systems are not 'designed' within their safety limit where thermal damage is concerned An overall conclusion with respect to intramedullary fixation of implants can be, that the [illegible]

[illegible] ments From the results of the parametric analyses it is evident that the following properties should then be specially evaluated with greater accuracy

- the thermal conductivity of the cement bone interface,
- the bone and local blood temperature prior to insertion of the cement,
- the heat transport mechanism at the bone surface,
- the thermal conductivity of cortical bone

be $\{1 - (1 + f_1)(1 + f_2)\})$ Results of applications for a few cases are shown in table 7 V In this table the influence of $T_{0b} = T_a$ is not taken into account In the reference case $T_{0b} = T_a = 37°C$, however, the local bone and blood temperatures during an operation are probably lower (d'Hollander *et al*, 1976)

Using the factors for the possible parameter ranges in fig 7 15, a possible' range in T_b and δ_m could be calculated also However, it is improbable, although possible, that an individual para meter has a value outside its probable range, but it is quite improbable that all parameters exceed their probable upper and lower boundaries simultaneously Moreover, since the combined in fluences were assumed to be independent in this calculation, it is doubtful whether, for such large deviations of the parameters from their reference values, such a calculation still has any realistic significance

Based on the data shown in table 7 V and the threshold curve in fig 3 1 the cautions con clusion can be drawn that, during fixation of intramedullary stems, tissue necrosis of the

TEMPERATURE VALUES DURING ACETABULAR CUP FIXATION

In this chapter a heat generation and conduction analysis of acrylic cement during acetabular cup fixation will be presented A schematic cross-section of the bone prosthesis system concerned is shown in fig 8 1 In the model used for the analysis the (plastic) cup, the cement layer and a part of the (spongeous) acetabular bone (as shown in fig 8 1) are taken into account Heat loss from the bone in the model to the adjoining bone or soft tissues is described by the boundary conduction and convection coefficient α The model is axisymmetric and although this does not give a very accurate geometrical description of the real system as far as the bone is concerned, it will at least give a more or less accurate description of the heat conduction process in the frontal plane

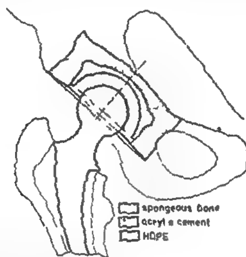

fig 8 1 Schematic frontal section of an acetabular cup fixation system, indicating the part of the acetabulum that is taken into account in the model

The model and its parameters are shown in fig 8 2, the parameter values used in the analysis are summarized in table 8.1

Fig. 8.3 shows the element mesh for the model, as generated by computer program (Schoofs et al 1978) T[illegible] dependent temperat[illegible] were cal[illegible]lated [illegible]

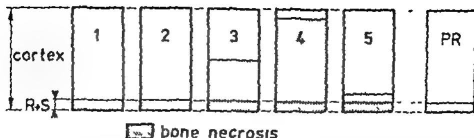

fig 7 16 Schematic summary of results reported by Feith (1 through 5) and an extrapola tion of results of the present work (PR), with respect to inner cortical necrosis of rabbit femurs after filling of the medular cavity with acrylic cement Parameters are reaming and suction (RS), residual monomer (M) and heat of polymerizing (H) 1 RS only, 2 RS + M, 3 RS + M + H, 4 RS + M (overdose), 5 RS + M + H (little heat), PR RS + H

hypothetical sixth group where reaming and suction and heat of polymerizing would be applied and in which, as was predicted by the rabbit model calculations, the amount of bone necrosis would be the same as in reaming and suction only

As there appears to be no reason to doubt the findings of Feith and because the present analysis has shown that the heat of polymerizing alone (a case that he did not investigate) would most probably not induce tissue necrosis in the rabbit, the hypothesis can be put forward, following directly from fig 7 16, that the necrotic effect of the residual monomer would be more pronounced at higher temperatures so that the temperature has an indirect effect rather than a direct effect

table 8.1: Values as used for parameters in the acetabular cup model.

From the calculated time dependent temperatures the liability of the bone to vascular damage or bone cell necrosis was estimated using the threshold level curves of fig 3 1, taking temperature values as well as the exposure times into account. From this evaluation a 'necrosis map' as shown in fig 8 7 evolves, also shown on this 'map' is the region in the cement that reaches over 100°C and would therefore be liable to monomer evaporation This 'necrosis map' gives an indication of the region most probably damaged and should not be regarded in too absolute a sense, since some parameter values are somewhat uncertain and the thermal damage threshold curves of fig 3 1 also have uncertain aspects If the data presented by Lundskog (1972) were taken as a threshold criterion (cell necrosis after exposure for 30 seconds to 50°C) a much larger part of the bone would be liable to necrosis, as indicated in fig 8.7.

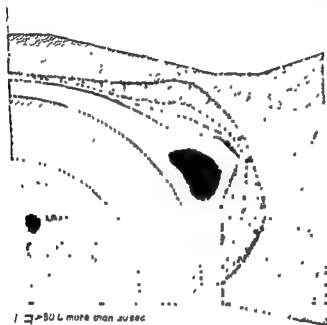

fig 8 7 A 'necrosis map as constructed from the calculated results, giving a rough impression of parts of the bone liable to osteocyte necrosis and vascular damage, using the time-dependent threshold levels in fig 3.1 as criteria, also indicated is the part of the bone that would be liable to osteocyte necrosis if the data of Lundskog (1972) were used as a criterion (necrosis after 30 sec at 50°C)

This model is not so well suited for extensive parametric analyses as the model discussed in [illegible]

[illegible] system is enclosed by much soft tissue and highly vascularized spongeous bone Thanks to the many and more dependable results published on the properties of spongeous bone,

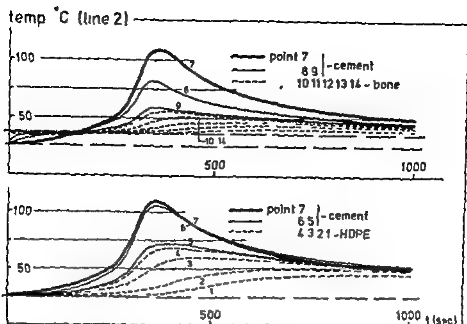

fig 8 5 Temperature as a function of time at the 14 points indicated in fig 8.4, as cal culated in the computer simulation (top graph cement and bone, bottom graph cement and cup, the temperature of point 7 (in the middle of the cement mass) is drawn in both graphs)

The temperatures in the HDPE are higher than those in the bone, due to the superior heat capacity and conductivity properties of the latter material, but also to the smaller area of the cup cement interface compared to the cement bone interface
For the three 'lines' shown in fig 8 4, time dependent penetration depths of the 45, 50, 55 and 60°C isotherms into the bone ($\delta(t)$) have been calculated, as shown in fig 8 6
On 'line' 3 especially, a relatively large part of the bone will be liable to tissue necrosis, as can be concluded on comparing these graphs with the time-dependent threshold level in fig 3 1 The high temperature values at 'line' 3 are caused by the circumstance that the bone is somewhat surrounded by cement here The lowest maximal temperature values are reached at 'line' 1, due to the relatively thin cement mantle in this region

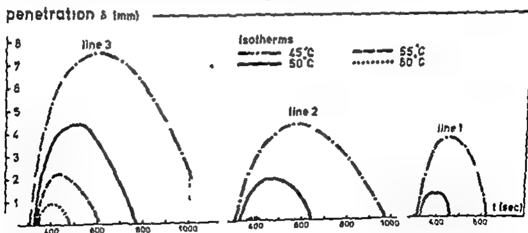

fig 8 6 Penetration depths of the 45, 50, 55 and 60°C isotherms into the bone on 'lines 1, 2 and 3 as functions of time

From the calculated time-dependent temperatures the liability of the bone to vascular damage or bone cell necrosis was estimated using the threshold level curves of fig 3 1, taking temperature values as well as the exposure times into account From this evaluation a 'necrosis map' as shown in fig 8 7 evolves, also shown on this 'map' is the region in the cement that reaches over 100°C and would therefore be liable to monomer evaporation This 'necrosis map' gives an indication of the region most probably damaged and should not be regarded in too absolute a sense, since some parameter values are somewhat uncertain and the thermal damage threshold curves of fig 3 1 also have uncertain aspects If the data presented by Lundskog (1972) were taken as a threshold criterion (cell necrosis after exposure for 30 seconds to 50°C) a much larger part of the bone would be liable to necrosis, as indicated in fig 8 7

compared to cortical bone, greater confidence can be given to the values of λ_b and C_b than in the previous model (see also table 5 VI) Inaccuracies in the predicted temperature values would thus for the greater part be due to uncertainty in the value of β Of course, it should not be forgotten that the geometry chosen for the model is a more or less general representation of the many possible ones in reality and that individual differences in maximal temperature values might thus occur to a greater or lesser extent
Due to variations in β only, the probable temperature increase in the bone could vary from approximately 0 8 to 1 0 times the calculated values Due to the fact that the cement is fixated to spongeous bone, somewhat lower values for β may be expected compared to those in the previous model

In conclusion it can be said that owing to geometrical circumstances, but also to a higher initial bone temperature and the inferior thermal properties of HDPE compared to metal, there will be a greater chance for thermal damage during acetabular cup fixation than during fixation of intramedullary (metal) implants If such damage occurs, a zone of about 1 - 2 mm will be affected, but in specific regions a larger zone (4 - 5 mm) may be liable to damage The chance of thermal necrosis can be reduced in this case, apart from the measures to be discussed in the next chapter, by smoothening the (macro) geometry of the bony implant bed and by avoiding the application of large cement masses

CHAPTER NINE

MEASURES FOR DIMINISHING THE CHANCES OF THERMAL TISSUE DAMAGE

As was shown in chapter 7, some options are available to reduce the maximal temperatures in the system, because the process of heat generation and conduction is quite sensitive to some of the parameters that can be influenced, either by the surgeon or by the cement manufacturer Experiments with a number of the possible measures have been published in the literature, for instance the addition of such 'heat sinks' as radiopaque fillers, titanium dioxide (Homsy *et al*, 1972), crystalline monomers (Lee and Turner, 1977) or aqueous gels (de Wijn *et al*, 1978), retardation of the polymerization curve (de Wijn, 1974) and pre cooling of the cement or the implant (Ohnsorge and Goebel, 1970, Meyer *et al*, 1973, Dipisa *et al*, 1976)

Some of the possible measures will be evaluated as to their effect on the maximal tempera ture values in the bone prosthesis system, on the basis of the parametric analysis discussed in chapter 7

9 1 Adding 'heat sinks' to the powder

When a heat sink is added to the powder, in other words, when a material with superior heat capacity properties is substituted for a part of the polymer powder, both the heat capacity and the thermal conductivity of the mixture are affected

If the weight ratio additive/powder is denoted by μ, the heat capacity C_c of the mixture can be calculated using formula (5 6) (paragraph 5 3) The influences of the changed value of C_c on the temperature increases (ΔT_c, ΔT_b) and the penetration depth of the 50°C isotherm (δ_m) in the model described in paragraph 7 1 can be evaluated using fig. 7 13 For added barium sulfate (ρ = 4 5x10^3 kg/m^3 C = 1 96x10^6 J/m^3°C) and zirconium oxide (ρ = 5 6x10^3 kg/m^3 C = 3 91x10^6 J/m^3°C) this evaluation was carried out neglecting the influence on the thermal conductivity and assuming a constant value of ν_m (0 35)

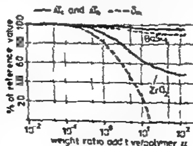

fig 9 1 Approximative influence of the amounts of barium sulfate and zirconium oxide added to the powder on the maximal temperature increase of the cement (ΔT_c), of the bone (ΔT_b) and on the penetration depth of the 50° isotherm, as percentages of the reference values (reference case ΔT_c = 101°C, ΔT_b = 22°C and δ_m = 1 5 mm). (100% = no additives)

compared to cortical bone, greater confidence can be given to the values of λ_b and C_b than in the previous model (see also table 5 VI) Inaccuracies in the predicted temperature values would thus for the greater part be due to uncertainty in the value of β Of course, it should not be forgotten that the geometry chosen for the model is a more or less general representation of the many possible ones in reality and that individual differences in maximal temperature values might thus occur to a greater or lesser extent
Due to variations in β only, the probable temperature increase in the bone could vary from approximately 0 8 to 1 0 times the calculated values Due to the fact that the cement is fixated to spongeous bone, somewhat lower values for β may be expected compared to those in the previous model

In conclusion it can be said that owing to geometrical circumstances, but also to a higher initial bone temperature and the inferior thermal properties of HDPE compared to metal, there will be a greater chance for thermal damage during acetabular cup fixation than during fixation of intramedullary (metal) implants If such damage occurs, a zone of about 1 2 mm will be affected, but in specific regions a larger zone (4 - 5 mm) may be liable to damage The chance of thermal necrosis can be reduced in this case, apart from the measures to be discussed in the next chapter, by smoothening the (macro) geometry of the bony implant bed and by avoiding the application of large cement masses

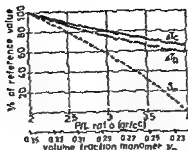

fig 9 3 Approximative influence of the P/L ratio on ΔT_c, ΔT_b and δ_m as percentages of the reference values (100% = 2 gr/cc)

9 4 Retarding the polymerization process

by using the polymerization functions p_1, p_2 and p_3 in chapter 7, on ΔT_c, ΔT_b and δ_m is shown in fig 9 4 where $1/\theta_p$ is chosen for the variable and 100% is taken for idealized snap curing cement For interpretation of these graphs it is convenient to note that when $1/\theta_p$ = 200 sec the auto acceleration period would be approximately twice as long compared to $1/\theta_p$ = 100 sec

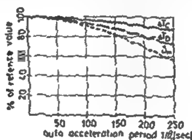

fig 9 4

9 5 Pre-cooling the operation region

As was shown in chapter 7, the bone temperature prior to insertion of the cement and the ambient (local blood) temperature exert a marked influence on the maximal temperatures in the bone It would be possible to cool the local operation region, prior to insertion, with a

For these two additives fig 9 1 shows the influence of the weight ratio μ on the cement temperature increase (ΔT_c), the bone(interface) temperature increase (ΔT_b) and the penetration depth (δ_m), expressed as percentages of their reference values, as evaluated in chapter 7 Evidently the addition of $BaSo_4$ has only a minor influence, adding ZrO_2 has considerably more effect However, for $\mu = 1$, the decrease in ΔT_c and ΔT_b is only about 10% and the decrease in δ_m about 20%

9 2 Adding an aqueous gel to the mixture

If an aqueous gel is added to the cement in other words, is substituted for a part of the cement, a porous cement will result when used for implantation (e g de Wijn *et al*, 1978) In this case the amount of heat generated per unit volume of mixture, the heat capacity of the mixture and the thermal conductivity are affected If it is assumed that the volume ratio between the polymer and the monomer remains constant, ν_m can be calculated for a given volume fraction of gel (ν_{ac}) by using formula (5 2) (paragraph 5 1) and C_c can be calculated using formula (5 7) (paragraph 5 3) For the thermal conductivity it is assumed that $\lambda_c = \lambda_c' + \nu_{ac} (\lambda_{ac} - \lambda_c')$, where λ_c' is the conductivity of only the acrylic part of the mixture Assuming that the influence of the changes in the three parameters are exerted independently, the effect of the changes combined can be approximated using the results described in chapter 7 This was carried out taking the thermal properties of the gel as those of water Fig 9 2 shows the influence of the volume fraction of gel in the mixture on the temperature increases ΔT_c and ΔT_b and the penetration depth δ_m, as percentage changes with respect to their reference value Apparently this measure has a marked influence on the temperatures

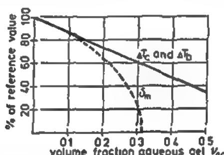

fig 9 2 Approximative influence of the amount of aqueous gel added to the cement mixture on ΔT_c, ΔT_b and δ_m as percentages of the reference values (100% = no gel added)

9 3 Increasing the P/L ratio

If the P/L ratio is increased, ν_m and hence Q are decreased The influence of this measure, that can be evaluated directly from figs 5 1 and 7 10, is shown in fig 9 3

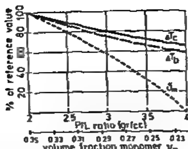

fig 9 3 Approximative influence of the P/L ratio on ΔT_c, ΔT_b and δ_m as percentages of the reference values (100% = 2 gr/cc)

9 4 Retarding the polymerization process

The polymerization function, especially the auto-acceleration effect, can be retarded with chemical additives (de Wijn, 1974) The auto acceleration effect is characterized by the maximal polymerization rate (θ_p = max(dp/dt)) The influence of retardation, as evaluated by using the polymerization functions p_1, p_2 and p_3 in chapter 7, on ΔT_c, ΔT_b and δ_m is shown in fig 9 4 where $1/\theta_p$ is chosen for the variable and 100% is taken for idealized snap curing' cement For interpretation of these graphs it is convenient to note that when $1/\theta_p$ = 200 sec the auto-acceleration period would be approximately twice as long compared to $1/\theta_p$ = 100 sec

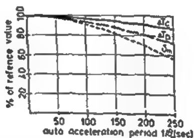

fig 9 4 Approximative influence of the rate of polymerization (the auto-acceleration effect) on ΔT_c, ΔT_b and δ_m, the variable on the horizontal axis is the inverse of the maximal polymerization rate (100% = 'snap-curing')

9 5 Pre-cooling the operation region

As was shown in chapter 7, the bone temperature prior to insertion of the cement and the ambient (local blood) temperature exert a marked influence on the maximal temperatures in the bone It would be possible to cool the local operation region, prior to insertion, with a

For these two additives fig 9 1 shows the influence of the weight ratio μ on the cement temperature increase (ΔT_c), the bone(interface) temperature increase (ΔT_b) and the penetration depth (δ_m), expressed as percentages of their reference values, as evaluated in chapter 7 Evidently the addition of $BaSo_4$ has only a minor influence, adding ZrO_2 has considerably more effect However, for $\mu = 1$, the decrease in ΔT_c and ΔT_b is only about 10% and the decrease in δ_m about 20%

9 2 Adding an aqueous gel to the mixture

If an aqueous gel is added to the cement, in other words is substituted for a part of the cement, a porous cement will result when used for implantation (e g de Wijn *et al*, 1978) In this case the amount of heat generated per unit volume of mixture, the heat capacity of the mixture and the thermal conductivity are affected If it is assumed that the volume ratio between the polymer and the monomer remains constant, ν_m can be calculated for a given volume fraction of gel (ν_{ac}) by using formula (5 2) (paragraph 5 1) and C_c can be calculated using formula (5 7) (paragraph 5 3) For the thermal conductivity it is assumed that $\lambda_c = \lambda_c' + \nu_{ac}(\lambda_{ac} - \lambda_c')$, where λ_c' is the conductivity of only the acrylic part of the mixture Assuming that the influence of the changes in the three parameters are exerted independently, the effect of the changes combined can be approximated using the results described in chapter 7 This was carried out taking the thermal properties of the gel as those of water Fig 9 2 shows the influence of the volume fraction of gel in the mixture on the temperature increases ΔT_c and ΔT_b and the penetration depth δ_m, as percentage changes with respect to their reference value Apparently this measure has a marked influence on the temperatures

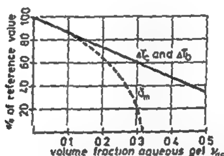

fig 9 2 Approximative influence of the amount of aqueous gel added to the cement mixture on ΔT_c, ΔT_b and δ_m as percentages of the reference values (100% = no gel added)

9 3 Increasing the P/L ratio

If the P/L ratio is increased, ν_m and hence Q are decreased The influence of this measure, that can be evaluated directly from figs 5 1 and 7 10 is shown in fig 9 3

Another possibility would be, where large cement masses are required, to use prefabricated plastic, for instance in coated stems

It should be noted that some of the possible measures affect the quality (strength) of the cement (see section I), for instance 'heat sink' additives to the powder, drastic increase of the P/L ratio and the addition of aqueous gels So they should not be applied over the full range of their possibilities

However, good results can be expected if some of the measures were taken in combination If 10 volume % aqueous gel were added to the mixture, the P/L ratio would be increased from 2 gr/cc to 2 25 gr/cc, the auto acceleration effect would be retarded by 100 sec and the operation region would be cooled to 30°C, prior to and during the polymerization, the maximal rise of the bone temperature would decrease by about 50%, thus in most cases banishing the chances of thermal bone necrosis completely

physiological water solution Fig 9 5 once more shows the effect of this measure on ΔT_c, ΔT_b and δ_m

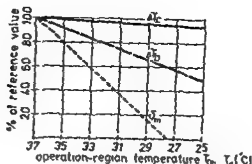

fig 9 5 Approximative influence of the bone and the local blood temperatures prior to the polymerization process on ΔT_c, ΔT_b and δ_m (100% = local bone and blood temperatures of 37°C)

9 6 Conclusions

Other measures than those discussed in this chapter would be possible, as for instance pre cooling of the cement and the implant Although this would certainly reduce the tempera ture values, it was shown in chapter 7 that, for instance pre cooling of the cement to 15°C has only a minor influence on the bone temperature, it was also shown in the literature (e g Ohnsorge and Goebel, 1970, Dipisa *et al*, 1976) that more drastic pre cooling seriously prejudices the polymerization process

Another possibility would be, at least in theory, to protect the bone by increasing the heat flow resistance at the cement bone interface, in other words, by decreasing β How this could be done in reality is not clear at the moment, some thin protective layer with low thermal conductivity would be the answer In this respect it can also be concluded that a thorough cleansing of the bony implant bed prior to cement insertion is not advantageous and would at least locally increase the chances of thermal bone necrosis An effective measure that could be taken by the surgeon as has been illustrated in chapters 7 and 8 is to avoid large cement masses and restrict the thickness of the cement layers Fig 9 6 once more shows the influences of the (metal) implant thickness (hence the cement mantle thickness) on ΔT_c ΔT_b and δ_m in intramedullary stem fixation

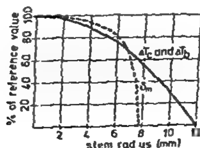

fig 9 6 Approximative influence of the (metal) stem thickness (hence also the cement layer thickness s) on ΔT_c, ΔT_b and δ_m (100% = no implant present)

with respect to the thermal threshold levels for cell necrosis are not significantly different (e g Kuhl *et al*, 1954, Lundskog, 1972, Feith, 1975) As was shown here, however, the differences in their levels more or less coincide with the upper and lower boundaries of the probable bone temperature values Hence, narrowing of this probable range would give no better answer More progress could be expected from applying more detailed theoretical analyses of the cement bone interface region, using the approximative results presented here as boundary conditions and combining the theoretical studies with experimental histological data

It was established that results of animal experiments are not representative of humans as far as heat generation and conduction aspects are concerned, owing to the differences in dimensions.

By simulating the rabbit experiments of Feith (1975) and combining the theoretical and experimental results, the hypothesis evolved that the temperature has an indirect effect, by means of the influences on the monomer reactions, rather than a direct effect on the tissue necrosis Whether this is true or not, it would in any case be better to reduce the temperatures as much as possible This can certainly be accomplished by *taking certain precautions In the* literature some possible ones have been investigated, the measures proposed were mostly partial and drastic, most often resulting in a cement of inferior quality It could be established here that certain quite simple and effective measures can be taken that will not prejudice the cement quality and that very good results can be expected if a number of slight measures are combined

The most remarkable influence is exerted by the local bone and blood *temperature prior to* cement insertion It should be quite possible to cool this region to 30°C *or even* 25°C, which will drastically decrease the maximal bone temperatures Also, the cement layer dimensions could be restricted as far as possible and the geometry of the implant bed could be made smooth and concave in the macroscopic sense

The in situ curing cement is in essence only needed to adapt the smooth implant to the *irregular bone* Hence the thickness of this cement layer would not *necessarily have to be* more than dictated by the dimensions of the irregularities Where only *fillings are required*, pre polymerized materials could be used as well

CHAPTER TEN

DISCUSSION

In this section the process of heat generation and conduction of acrylic cement in situ ha been analysed By making certain assumptions as to the properties of the cement and the bone material, and by approximating the geometry of the bone prosthesis system by axi symmetry, the heat generation and conduction process was mathematically described on the basis of the conservation of energy principle and Fourier's law The equations have be solved using a computer program applying FEM and backward time discretization Based a literature review, values for parameters used in the models were estimated Relatively lit was found to be known about these parameters, hence, in some cases only a range of probable values could be established This range will, no doubt, also reflect the individual differences where biological material is concerned and random compositional differences where acrylic cement is concerned Due to the uncertainties as regards parameter values t use of more refined mathematical models would, in this respect, not be justified as yet Unfortunately, the influence of the temperature on the polymerization process itself coul not be taken into account, owing to lack of knowledge about this relation, in the mathe matical model and the solution procedure chosen here this influence can easily be account for By simulation of two experiments published in the literature, the applicability of the model and the appropriateness of the chosen parameter values have been evaluated to som extent and it was shown that the method can in fact be used to predict the time dependen temperature values by approximation Based on a literature review, threshold levels for thermal tissue damage were evaluated As was to be expected here, too, no exact value for this level evolved Taking the upper and lower boundaries of all dependable published data one could say that for a bone temperature above 60°C bone necrosis is probable and for a temperature below 48°C it is improbable Between 48 and 60°C it depends on the exposur time, for a temperature of 50°C the threshold exposure time may be between 30 sec (Lundskog, 1972) and 400 sec (Moritz and Henriques, 1947) as regards cell necrosis In analyzing a number of situations in which bone cement is used for fixation of implants it was found that the maximal bone temperature values to be expected are precisely within this range Because of this, no definite answer can be given to the question whether therma damage occurs or not, the possibilities certainly exist and much will depend on the specific circumstances No doubt this is also the reason for the variety in results of animal and labo- ratory experiments, published on this problem

It was shown that in surface fixation using plastic implants for instance the acetabular cup [illegible] med the f xation using metal [illegible] not be higher than [illegible] re were probably measured in the cement part of the cement bone interface Very high tempe ratures will only occur locally, in the tips of trabeculae surrounded by cement
More definite data could be obtained in using the methods described here if certain proper ties of the bone prosthesis system were established with better accuracy by experiment Guidelines for such experiments, as followed from the analyses, have been discussed in chapter 7 Due to individual differences and random influences, however, a considerable scatter in the data will always remain It is, for instance, frequently mentioned in the litera ture that the results of Moritz and Henriques (1947), Kuhl *et al* (1954) and Lundskog (1972,

STRESS ANALYSES OF INTRAMEDULLARY FIXATION SYSTEMS

CONTENTS

CONTENTS

LIST OF SYMBOLS

In the following list of symbols, where i or j occur as indices, they either denote b (for bone), c (for cement) or s (for stem)

geometrical parameters

L_b	mm	bone length
L	mm	*fixated stem length*
L_f	mm	free stem length
r_s	mm	stem radius
d_s	mm	stem diameter
r_b	mm	inner bone radius
d_b	mm	inner bone diameter
r_o	mm	outer bone radius
d_o	mm	*outer bone diameter*
ρ	mm	ratio r_s/r_b
γ_s	mm	outer circumference of the stem
γ_b	mm	inner circumference of the bone
d	mm	stem thickness in y direction (plane model), *see paragraph 5 5*

reference systems

x, y, z	mm	rectangular coordinate system
r, φ, z	mm	cylindrical coordinate system
ξ	mm	coordinate in negative z direction ($\xi = L - z$), *see paragraph 5 3*

materials properties

E_i	N/mm²	Young's modulus
ν_i	-	Poissons's ratio

loading parameters

X	N	*force on the proximal end of the free stem region in* negative x direction (see fig 3 1)
Z	N	force on the proximal end of the free stem region in *negative z direction (see fig 3 1)*
M	Nmm	bending moment on the proximal end of the free stem *region around the y axis (see fig 3 1)*
$M_i(z)$	Nmm	bending moment in bone, layer or stem

$M(z)$	Nmm	total bending moment in cross section ($M = M_b + M_s + M_c$)
M_L	Nmm	bending moment in the stem, at $z = L$ (fig 5 8)
M_0	Nmm	bending moment in the bone, at $z = 0$ (fig 5 8)
$N_i(z)$	N	normal (axial) force in bone, layer or stem (positive z-direction)
$N(z)$	N	total normal force in cross-section ($N = N_b + N_s + N_c$)
N_L	N	normal force in the stem at $z = L$ (see fig 5 11)
N_0	N	normal force in the bone, at $z = 0$ (fig 5 11)
$T_i(z)$	N	transverse force in bone, layer or stem (positive z direction)
$T(z)$	N	total transverse force in cross section ($T = T_b + T_s + T_c$)
T_L	N	transverse force in the stem, at $z = L$ (see fig 5 8)
T_0	N	transverse force in the bone, at $z = 0$ (see fig 5 8)
$p_s(z)$	N/mm	continuously distributed transverse load exerted by the cement layer on the stem (fig 5 9)
$p_b(z)$	N/mm	continuously distributed transverse load exerted by the cement layer on the bone (fig 5 9)
$p(z)$	N/mm	as p_s and p_b, if both are assumed equal
$q_s(z)$	N/mm	continuously distributed shearing load exerted by the cement layer on the stem (fig 5 11)
$q_b(z)$	N/mm	continuously distributed shearing load exerted by the cement layer on the bone (fig 5 11)
$q(z)$	N/mm	as q_s and q_b, if both are assumed equal

displacements

$u_s(z)$	mm	deflection of the stem neutral axis in x-direction
$u_b(z)$	mm	deflection of the bone neutral axis in x-direction
$w_s(z)$	mm	displacement of the stem in z-direction
$w_b(z)$	mm	displacement of the bone in z-direction

cross sectional parameters

A_i	mm^2	cross sectional area
W_i	mm^3	moment of resistance
I_i	mm^4	second moment of inertia
P_i	N	compressional stiffness ($P_i = E_i A_i$)
F_i	Nmm^2	flexural stiffness ($F_i = E_i I_i$)
C_a	N/mm^2	stiffness of the cement layer against axial loading (shear)
C_t	N/mm^2	stiffness of the cement layer against transverse loading
λ_a	mm^{-1}	coefficient for axial loading
λ_t	mm^{-1}	coefficient for transverse loading

stress parameters

$\sigma_r, \sigma_t, \sigma_z$	N/mm^2	direct stresses (table 3 III)
$\tau_{rt}, \tau_{rz}, \tau_{tz}$	N/mm^2	shear stresses (table 3 III)
$\hat{\sigma}, \hat{\tau}$	N/mm^2	stress 'amplitudes' (paragraph 5 1)
σ_1, σ_2	N/mm^2	principal stresses
σ_{eq}	N/mm^2	equivalent stress (chapter 3)
$s_{zi}(z)$	N/mm^2	maximal axial stress (σ_z) in a cross section
$\bar{s}_{ri}(z)$	N/mm^2	average normal stress in transverse direction at the stem cement interface (s) or at the cement bone interface (b) (paragraph 5 2 1)
$t_i(z)$	N/mm^2	axial shear stress at the stem cement interface (s) or at the cement bone interface (b) (paragraph 5 2 2)

others

$g(\nu_c)$	–	expression in ν_c (appendix B)
c_1, c_2	–	constants (appendix B)
α, β, ϵ	–	factors (paragraph 7 1)

CHAPTER ONE

INTRODUCTION

The question as to whether a specific structure will fail or not depends on two different sets of properties First, the strength of the structure, in this case of the implant, the cement layer, the bone and the connection between these components, second, the loading of the structure in a local sense, in other words the stress distribution This last depends solely on the loading of the structure (the joint loading), the geometry of the structure, the constitutive properties of the materials (for instance their elasticity) and the conditions at the connections of the components (the interfaces)
The strength characteristics of the components can be evaluated by applying laboratory materials testing, the stress distribution by applying stress analyses, either experimental or theoretical Theoretical analyses may either be analytical, in which case the stress components are directly expressed in formulas that contain the loading, geometrical and materials parameters (closed form solutions), or numerical, in which case the solution is not available in closed form, but obtained by applying numerical (computer) procedures Regarding experimental stress analyses, different methods are available (Durelli, 1977) of which only a few are suitable to be used for bone prosthesis structures (e g strain gauges, stress coating, photo-elastic techniques)
It should be the aim of a stress analysis not only to evaluate the stress distribution in specific circumstances but also to obtain general, fundamental concepts on the relation between the stresses and the loading, geometrical and materials properties or, in other words, to find the characteristic parameters of the structure and evaluate their influences on the mechanical behavior This aim is best fulfilled by using analytical methods, since in that case the characteristic parameters and variables are directly related in formulas However, closed form solutions can usually only be obtained for [illegible]

[illegible]

[illegible] they thus offer only limited options for acquiring fundamental and general data (Huiskes and v Heugten, 1974)

To conduct a theoretical stress analysis, analytical or numerical, a mathematical model of the structure has to be developed which describes its mechanical behavior to an adequate degree [illegible]

[illegible]

- the irregular geometry of the bone,
- the nonhomogeneous, anisotropic and viscoelastic properties of the bone tissue,
- the dynamic character of the joint loading,
- locked in stresses in the cement mantle, caused by dimensional changes during the polymerization process,
- the complicated mechanical conditions of the cement stem and cement bone contact regions, the interfaces , where loosening upon tension and slip may occur

Even if a model taking these complicated properties into account can be set up, it will be difficult to establish the values of the parameters that have to be used in the calculations

stress parameters

$\sigma_r, \sigma_t, \sigma_z$	N/mm²	direct stresses (table 3 III)
$\tau_{rt}, \tau_{rz}, \tau_{tz}$	N/mm²	shear stresses (table 3 III)
$\hat{\sigma}, \hat{\tau}$	N/mm²	stress 'amplitudes' (paragraph 5 1)
σ_1, σ_2	N/mm²	principal stresses
σ_{eq}	N/mm²	equivalent stress (chapter 3)
$s_{zi}(z)$	N/mm²	maximal axial stress (σ_z) in a cross section
$\bar{s}_{ri}(z)$	N/mm²	average normal stress in transverse direction at the stem cement interface (s) or at the cement bone interface (b) (paragraph 5 2 1)
$t_i(z)$	N/mm²	axial shear stress at the stem cement interface (s) or at the cement bone interface (b) (paragraph 5 2 2)

others

$g(\nu_c)$	–	expression in ν_c (appendix B)
c_1, c_2	–	constants (appendix B)
α, β, ϵ	–	factors (paragraph 7 1)

CHAPTER TWO

REVIEW OF LITERATURE ON RELEVANT THEORETICAL STRESS ANALYSES

Scientists have long been interested in stresses and strains in human bones The first sophisti cated stress analysis of a human bone, the proximal femur, was published by Meyer in 1867 This work was repeated and extended by Wolff (1870) and resulted in the well known hypo thesis on the functional stress-related adaption of the bone structure Koch (1917) confirmed this hypothesis after analyzing a cadaveric femur with beam theory and promoted it to Wolff's law' Beam theory was later used for stress analyses of the human femur by Toridis (1969), this time taking three-dimensional loading and geometry into account, by Rybicki *et al* (1972), who compared the results with more sophisticated stress analyses methods (Finite Elements), and by Scholten (1975), who took three dimensional geometry and non *homogeneous* material properties into account and also applied Finite Element Methods Although frequently used, it has not been verified whether the assumptions of linear elastic beam theory apply to the mechanical behavior of the femur a problem investigated in our group and which will be discussed briefly in chapter 4

As in other areas of solid mechanics, biomechanics research has greatly benifited *from the introduction of* Finite Element Methods (FEM), a computer-oriented method for stress analyses, eminently suitable for arbitrarily shaped structures with arbitrary loading and materials properties (e g Zienkiewicz, 1977) This method was introduced *into the ortho pedic biomechanics* field as an expedient for structural analyses of bone, by Brekelmans *et al* (1972) and Rybicki *et al* (1972) simultaneously Both presented relatively simple plane stress models of the femur FEM models developed in later years by other investigators became more refined, especially in their geometrical aspects With few exceptions all con cerned the femur

Wood *et al* (1973, 1975) presented a plane stress model of the proximal femur, *taking non-*uniform thickness into account Olofsson (1975, 1976) *analyzed a truly* three dimensional FEM model of the intact femur The problems of data manipulation, *interpretation and* representation that are still connected with such complex models, are reflected in his work His calculations took up huge amounts of computer *time, leaving few* possibilities for para metric analyses.

Quite refined and accurate two-dimensional and three dimensional FEM models of the proximal femur were developed by Scholten (1975) *Geometry* and elastic properties (non homogeneous) were exclusively measured *for these calculations* The results were compared with beam models an example of which is shown in fig 2 1

A somewhat less refined three-dimensional *model was reported by* Vall [illegible]

They var [illegible]

[illegible]

t ex. A tr [illegible] the femur was carried out by Vichnin and Batterman (1977), who used *geometrical* data measured by Laaper (1973a)

Harris *et al* (1978) too, *analyzed a three-dimensional* model of the proximal femur and compared the results with a two-dimensional *and a* beam model, agreements appear to be reasonable

Moreover, the relations between such a refined model and the real structure will be badly defined, because

- bone geometry, bone material properties and loading characteristics vary considerably from patient to patient,
- the mechanical characteristics of the bone prosthesis structure depend on the surgical procedure, which may vary to a great extent,
- the bone geometry, the bone material properties and the interface conditions may undergo gradual postoperative change due to bone remodeling

Altogether, a detailed accurate theoretical analysis of the mechanical behavior of specific bone prosthesis structures is an unrealistic goal as yet However, general, fundamental concepts of the influences of the essential characteristics of such a structure can be obtained and tendencies can be studied by analyzing simplified models using both analytical and numerical methods, as will be shown in this section

A survey of the literature on previous work is given in the following chapter

In the third chapter a simplified (general) model of intramedullary fixation systems is introduced This model is analyzed using different methods, as described in chapter 5 The analyses provide the essential characteristics of the bone prosthesis structure and a number of simple formulas to approximate the most important stress values in the stem, the cement and the bone A simple and rapid numerical evaluation method for specific stem designs and their expected mechanical performance in a given bone will also be developed

Results of an experimental stress analysis, that serve as references for the theoretical results will be briefly discussed in the fourth chapter

The theoretical model is an abstraction of the real system, of which many complicated aspects are neglected The possible influences of these aspects are discussed in chapter 6

In the last chapters some guidelines will be given for implant designs and implantation procedures as derived from the analyses Due to the fact that the hip joint is by far the one most often replaced and that most data available concern the proximal femur, the following analyses are focussed on hip endoprostheses It should be kept in mind, however, that the methods and some of the results can be generalized to apply to other intramedullary fixated artificial joints as well

A simplified axisymmetric model of an intramedullary fixation system using three dimensional FEM and composite beam theory was analyzed by Bartel and Ulsoy (1975), Bartel and Samehyek (1976), Bartel and Desormeaux (1976a, 1976b) Thanks to a reduction in the number of geometrical parameters, these studies resulted in a more general comprehension of the mechanical behavior than did other, more complicated studies.
Andriacchi *et al* (1975) used a plane stress FEM analysis to study the proximal femur with different kinds of prostheses implanted in neutral, varus and valgus positions Since in their model there was no connection between the medial and the lateral cortex, they in fact analyzed a kind of sandwich construction that can hardly be expected to be a reliable representation of the real system, as will be discussed in paragraph 5 5
The same method was applied by Kwak *et al* (1979), who studied the influences of the cement layer thickness in a two dimensional FEM model of the proximal femur with an implanted Charnley prosthesis
A better method was presented by Hampton *et al* (1976) who analyzed a comparable plane stress model, but took the full stiffness properties of the femur into account by modeling a side plate or 'spanning-element' layer between the medial and the lateral cortex They also developed a three dimensional FEM model of the same structure
Svensson *et al* (1977) presented a two-dimensional FEM model, taking three-dimensional geometry into account and also using 'spanning element' layers to model the medial lateral bone connection They found a reasonable qualitative agreement between the calculated stresses at the bone surface and results of stress-coating experiments carried out by Brockhurst (1975) They simulated different stem designs and elastic layer properties and concluded that, by using a thick stem, most of the critical stresses will be reduced They were the first to investigate the influences of the interface conditions In one calculation they assumed the stem cement connection as allowing slip and no tension and found a completely different stress distribution at the interfaces compared to the results of calculations in which the materials were assumed to be rigidly connected

fig 2 2 Element mesh of a three-dimensional FEM model of the proximal femur with implanted hip prosthesis This and comparable models, analyzed by Rohrle et al (1977, 1979) and Scholten et al (1978) are the most detailed ones in the present literature with respect to geometrical and material representation (reproduced with permission of Rohrle et al, 1979)

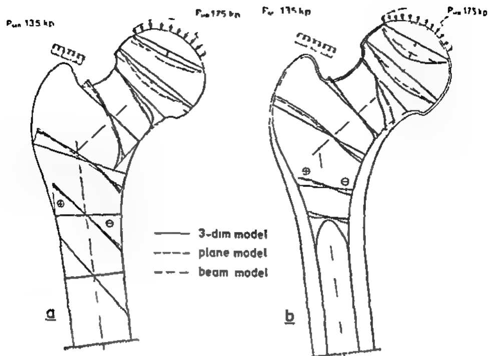

fig 2 1 Comparison of a three dimensional FEM model, a two dimensional FEM model and a beam model of the proximal femur Axial direct stresses in the cortex (a) and in the spongeous bone (b) are shown The plane shown is a plane of symmetry in the three models Up to the neck region the agreement is rather good (reproduced with permission of Scholten, 1975)

With the object of verifying certain assumptions in the process of modeling, Rohlmann *et al* (1977, 1978) analyzed a longitudinal slice of the femur, using FEM and strain gauges They also analyzed a three dimensional model with FEM (Rohlmann *et al*, 1979), the results of which they compared with those of strain gauge experiments on a cadaveric femur They found poor agreement in the absolute sense and concluded that in a FEM model a quite refined element mesh should be used, the boundaries between spongeous and cortical bone should be accurately evaluated and modeled and the exact ratio of stiffness properties should be taken into account
Apart from the femur, the tibia has received some attention in structural analysis Chand *et al* (1976) published a two dimensional FEM analysis of the knee joint and Hayes *et al* (1978) reported a three dimensional analysis of an axisymmetric model of the proximal tibia The full tibia was analyzed by Piziali *et al* (1976) and by Minns *et al* (1977)

In the meantime theoretical stress analyses of bone prosthesis structures were published, again usually on the femoral part of the hip joint A plane stress FEM model of the proximal femur with three different types of prostheses was reported by McNeice *et al* (1975) and McNeice and Amstutz (1976) Based on their studies they defined 4 different failure modes for cement fracture, which they later used to evaluate results of total hip replacements radiographically (McNeice and Gruen, 1976, Gruen and Amstutz, 1977) Their model will be discussed further in paragraph 5 5
Forte (1975) carried out a FEM beam analysis of a prosthesis stem with the object of optimizing its shape, a quite unrealistic model, since the important mechanical interaction with the bone was completely ignored

A simplified axisymmetric model of an intramedullary fixation system using three dimensional FEM and composite beam theory was analyzed by Bartel and Ulsoy (1975), Bartel and Samehyek (1976), Bartel and Desormeaux (1976a, 1976b) Thanks to a reduction in the number of geometrical parameters, these studies resulted in a more general comprehension of the mechanical behavior than did other, more complicated studies

Andriacchi *et al* (1975) used a plane stress FEM analysis to study the proximal femur with different kinds of prostheses implanted in neutral, varus and valgus positions. Since in their model there was no connection between the medial and the lateral cortex, they in fact analyzed a kind of sandwich construction that can hardly be expected to be a reliable

implanted Charnley prosthesis

A better method was presented by Hampton *et al* (1976) who analyzed a comparable plane stress model, but took the full stiffness properties of the femur into account by modeling a side plate or spanning-element' layer between the medial and the lateral cortex They also developed a three dimensional FEM model of the same structure

Svensson *et al* (1977) presented a two-dimensional FEM model taking three dimensional geometry into account and also using spanning element layers to model the medial lateral bone connection They found a reasonable qualitative agreement between the calculated stresses at the bone surface and results of stress coating experiments carried out by Brockhurst (1975) They simulated different stem designs and elastic layer properties and concluded that by using a thick stem, most of the critical stresses will be reduced They were the first to investigate the influences of the interface conditions In one calculation they assumed the stem cement connection as allowing slip and no tension and found a completely different stress distribution at the interfaces compared to the results of calculations in which the materials were assumed to be rigidly connected

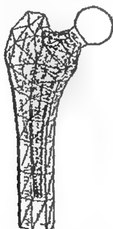

fig 2 2 Element mesh of a three-dimensional FEM model of the proximal femur with implanted hip prosthesis This and comparable models, analyzed by Rohrle et al (1977 1979) and Scholten et al (1978) are the most detailed ones in the present literature with respect to geometrical and material representation (reproduced with permission of Rohrle et al, 1979)

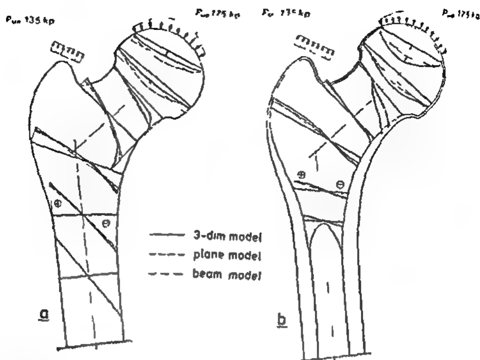

fig 2 1 Comparison of a three dimensional FEM model, a two dimensional FEM model and a beam model of the proximal femur Axial direct stresses in the cortex (a) and in the spongeous bone (b) are shown The plane shown is a plane of symmetry in the three models Up to the neck region the agreement is rather good (reproduced with permission of Scholten, 1975)

With the object of verifying certain assumptions in the process of modeling, Rohlmann *et al* (1977, 1978) analyzed a longitudinal slice of the femur, using FEM and strain gauges They also analyzed a three dimensional model with FEM (Rohlmann *et al*, 1979), the results of which they compared with those of strain gauge experiments on a cadaveric femur They found poor agreement in the absolute sense and concluded that in a FEM model a quite refined element mesh should be used, the boundaries between spongeous and cortical bone should be accurately evaluated and modeled and the exact ratio of stiffness properties should be taken into account

Apart from the femur, the tibia has received some attention in structural analysis Chand *et al* (1976) published a two dimensional FEM analysis of the knee joint and Hayes *et al* (1978 reported a three dimensional analysis of an axisymmetric model of the proximal tibia The full tibia was analyzed by Piziali *et al* (1976) and by Minns *et al* (1977)

In the meantime theoretical stress analyses of bone prosthesis structures were published, again usually on the femoral part of the hip joint A plane stress FEM model of the proximal femur with three different types of prostheses was reported by McNeice *et al* (1975) and McNeice and Amstutz (1976) Based on their studies they defined 4 different failure modes for cement fracture, which they later used to evaluate results of total hip replacements radiographically (McNeice and Gruen, 1976, Gruen and Amstutz, 1977) Their model will be discussed further in paragraph 5 5

Forte (1975) carried out a FEM beam analysis of a prosthesis stem with the object of optimizing its shape, a quite unrealistic model, since the important mechanical interaction with the bone was completely ignored

Because of the many complicated features of bone prosthesis structures and the usually uncertain numerical values of parameters, one cannot expect to be able to develop a mathematical model that will predict the stress distribution in the real structure in an absolute sense This fact is recognized by most of the authors previously cited and it is often remarked that, because of the possibilities for parametric analyses in the models, they can still contribute to a better comprehension of the mechanical behavior Although this is true in general, the overall picture of the work previously discussed is rather confusing This is due to the fact that many of the complex models used are rather specific and little is known about the influences of simplifying assumptions, this often places the analysis procedures in a frame of 'numerical empiricism' (Oden and Bathe, 1978) and results in anything but general concepts Hence, the results of the analyses are sometimes in conflict and are usually quite specific To acquire more general data a model should be relatively simple, with options for either extensive parametric analysis or closed form solutions Therefore, detailed three-dimensional FEM models are not very suitable to fulfil this aim due to their complexity and also, at least contemporarily, to the excessive computer time and data manipulation efforts needed, thus limiting the possibilities for extensive parameter variation Moreover, it appears to be rather illogical to use a model that is quite refined in its geometrical aspects, while rough in the other aspects, such as those summarized in chapter 1

In short, it is evident that although many significant contributions to insight in the mechanical behavior of intramedullary bone prosthesis structures have been presented in the literature, there is a need for more general and fundamental concepts on the relations between structural parameters and mechanical performance It was the object of the work presented in this section to find the essential characteristics of the structure and to provide such concepts

Probably the most detailed FEM analyses of the proximal femur with implanted prostheses were carried out by Rohrle *et al* (1977, 1979) and Scholten *et al* (1978) Their models were truly three dimensional, using adequately refined element meshes (fig 2 2), non homogeneous bone properties were taken into account as well as three dimensional loading Interfaces were modeled as either allowing or not allowing slip and otherwise rigidly connected These models were used in comparative studies to evaluate specific designs and to answer specific questions with respect to design features as, for instance the influences of calcar support or the stiffness of the intermediate layer
Another three dimensional FEM analysis of the proximal femur with an implanted hip prosthesis was reported by Crowninshield *et al* (1979), who had earlier analyzed the influences of cross sectional stem shapes (Crowninshield and Branch, 1978) They carried out parametric analyses, varying Young's moduli of stem and cement, stem thickness and stem length Based on their results they advocate a decrease of cement stiffness and an increase of stem length, thickness and stiffness in order to decrease the cement stresses Their calculations were compared to simple strain gauge experiments, resulting in qualitatively reasonable agreement for femoral surface stresses In their model the different materials were assumed to be rigidly connected at the interfaces
A detailed three dimensional FEM analysis was reported by Tarr *et al* (1979) In a model using a rather coarse element mesh, a cobalt chromium and a more flexible titanium alloy stem were simulated They found that stresses in the stem and in the distal cement layer were lower with the titanium alloy, while stresses in the proximal cement layer were higher Comparison of results with a simple strain gauge experiment on a cadaveric femur gave poor absolute, but reasonable qualitative agreement

An interesting venture was undertaken by Rohlmann *et al* (1979), who analyzed a model of a hip endoprosthesis cemented into a brass tube, using three dimensional FEM (a model with 1600 degrees of freedom) and also strain gauge experiments They found rather poor continuity of stresses at the interfaces in the calculations and only moderate agreement between experimental and theoretical results, both of which they ascribed to the coarseness of the element mesh, indicating that in the three dimensional FEM models quite a high level of mesh refinement is needed
Another approach to structural analysis of intramedullary fixation systems was followed by an Italian group (Calderale *et al*, 1977, Barberi *et al*, 1978, Gola and Gugliotta, 1979), who modeled the femur and the prosthesis stem as cantilever beams, coupled by an elastic (cement) layer The model was analyzed numerically, using minimal potential energy criteria The model can be applied for transverse loading only The stiffness of the elastic layer was evaluated experimentally Although the information resulting from analyses of this kind is limited, they are quite simple and can conveniently be used for a first-order rapid evaluation of stem designs

Where intramedullary fixation is concerned, few efforts have been put into sophisticated theoretical analyses of other than hip endoprostheses Van Campen *et al* (1978 1979) [illegible] of a hinged

[illegible] is

[illegible] *al*, 1979)

Theoretical stress analyses of other than [illegible] prostheses at least not mainly fixated in this manner, have been carried out for tibial components of artificial knee joints (Chao *et al*, 1977, Lewis, 1977, Askew *et al*, 1978, 1979, Hayes, 1978) and for the hip surface replacement (v Heck and Huiskes, 1979)

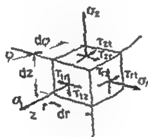

fig 3 2 The nine components of the stress tensor in a cylindrical coordinate system (r, φ, z)

The state of stress at a point of the structure is described by the three dimensional stress tensor in a cylindrical coordinate system (r, φ, z) as shown in fig 3 2 The stress components are described in table 3 III Due to the action = reaction law some stress components have to be continuous across the stem cement and cement bone interfaces, in this model these components are σ_r, τ_{rt} and τ_{rz}

Due to compatibility requirements and differences in elastic moduli of the materials, the other stress components have to be discontinuous across the interfaces In order to be able to judge the stress state at a point of the structure or simply to reduce the amount of data describing the stress state, an equivalent stress based on a certain failure criterion can be

CHAPTER THREE

A SIMPLIFIED MODEL OF INTRAMEDULLARY FIXATION STRUCTURES

The model is shown in fig 3 1 It consists of an axisymmetric 'bone' with an axisymmetric intramedullary stem Both the stem and the bone have constant cross sectional properties

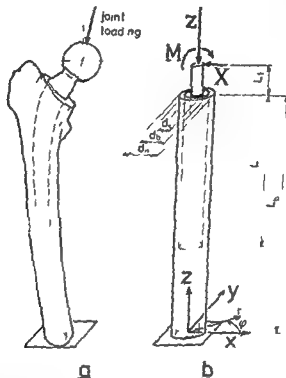

fig 3 1 The axisymmetric model (b) of an implanted hip endoprosthesis (a) geometrical parameters coordinate systems and loading are shown

Between the stem and the bone a layer of acrylic cement, rigidly connected to both the stem and the bone is assumed Although the model can be regarded as a general one for any intramedullary fixation structure, the dimensions were chosen according to the hip endoprosthesis as more-or less average as reported in the literature (Kempf et al, 1976, Laaper, 1973a, Huiskes and Slooff, 1979b) Although dimensions will be varied in the calculations, a set of what will be referred to as 'reference values' is shown in table 3 1
The stem layer and bone materials are assumed as behaving linear elastic isotropic and [illegible] or less

A three dimensional state of loading on the stem is [illegible] (Z), a transverse force (X) and a bending moment (M) The stress analyses are carried out for each of these loading cases separately Since the stresses and deformations in the structure, because of the linear assumptions, are proportional to the load magnitudes these were chosen arbitrarily as 1,000 N, 100 N and 10,000 Nmm respectively

CHAPTER FOUR

AN EXPERIMENTAL STRESS ANALYSIS OF A CADAVERIC FEMUR WITH IMPLANTS

Apart from theoretical stress analyses, as reviewed in chapter 2, also experimental stress and strain analyses of bones, both intact and provided with implants, have been reported Brittle coating, photo elastic, optical and strain-gauge techniques have been used Many strain-gauge experiments concerning intramedullary fixation structures have been reported recently, devoted, with few exceptions (e g v Campen *et al*, 1978, 1979) to the proximal femur with hip endoprostheses
The first experiments of this kind were carried out in our group (Slooff, 1970, 1971, Brekelmans en Poort, 1973, v Heugten, 1974, Huiskes *et al*, 1976, Huiskes, 1978, Huiskes and Slooff, 1979b) Strains were measured on the outside surface of the loaded femur, intact as well as provided with implants Comparable experiments were conducted by Oh and Harris (1978) who applied only a few strain gauges, but carried out measurements on different bones with different prostheses, by Huggler *et al* (1978) who also attached strain gauges to the prosthesis stem, and by McBeath *et al* (1979) As discussed in chapter 2, more of these experiments have been carried out specifically to verify theoretical results

The experiments conducted by our group concerned the cadaveric femur of a 52 yr-old man To the femur, kept in formaline, 112 rosette strain gauges were attached (fig 4 1 a) Forces on the head in 3 perpendicular directions and couples in 3 planes were applied separately in turn (fig 4 1 b)
To calculate the measured strain values (three for each strain gauge) to principal stresses, linear elasticity, homogeneity and isotropy was assumed, the bone Young's modulus was taken as 20,000 N/mm^2 and its Poisson's ratio as 0 37
Equivalent stresses were calculated using the maximal deformational energy criterion of Maxwell Huber Hencky Von Mises It should be noted that with such an experimental method the complete strain distribution in the structure can *not be measured*, but only the strain state at the outside surface The stresses, calculated from the experimental data, were compared to the corresponding values of stresses as calculated for the model, *in this case* σ_t, σ_z and $\tau_{zt} = \tau_{tz}$ at the outside surface of the bone
It was found that in loading by pure couples (up to 12,500 Nmm) the bone showed *linear* elast c behav or

..., however, after 3½ min of constant loading the strains stabilized to constant values. The reproduceability of the *strain* measurements was better than 5%, even after 2½ years

calculated from the six independent stress components Here the maximal deformational energy criterion is used, according to Maxwell Huber Hencky Von Mises

$$\sigma_{eq} = \sqrt{[\{(\sigma_r-\sigma_t)^2 + (\sigma_r-\sigma_z)^2 + (\sigma_t-\sigma_z)^2\}/2 + 3(\tau_{rt}^2 + \tau_{rz}^2 + \tau_{tz}^2)]}$$

It should be remarked here, that his equivalent stress has proven its value as a yield crite rion for such materials as stainless steel Although it will probably give an indication of the stress state in cement or bone, its value as a yield criterion for these materials is uncertain

The model presented here will be analyzed using different analytical as well as numerical methods (FEM), as described in chapter 5
It cannot be expected that with such a simplified model the stress distribution in the real structure can be predicted accurately in an absolute sense, which is obviously not the object of the investigation It is expected, on the other hand, that the structure is described by the model in a qualitative sense In order to roughly verify this expectation, the calculated results are compared to results of strain gauge experiments that will be discussed briefly in the next chapter In chapter 6 the influences of system parameters that are neglected in this simplified model (thermal stresses, interface loosening nonconstant cross sectional properties of the structure, the occurrence of torsional loading and a few others) will be evaluated or at least discussed

CHAPTER FOUR

AN EXPERIMENTAL STRESS ANALYSIS OF A CADAVERIC FEMUR WITH IMPLANTS

Apart from theoretical stress analyses, as reviewed in chapter 2, also experimental stress and strain analyses of bones, both intact and provided with implants, have been reported Brittle coating, photo-elastic, optical and strain gauge techniques have been used Many strain gauge experiments concerning intramedullary fixation structures have been reported recently, devoted, with few exceptions (e g v Campen *et al*, 1978, 1979) to the proximal femur with hip endoprostheses
The first experiments of this kind were carried out in our group (Slooff, 1970, 1971, Brekelmans en Poort, 1973, v Heugten, 1974, Huiskes *et al*, 1976, Huiskes, 1978, Huiskes and Slooff, 1979b) Strains were measured on the outside surface of the loaded femur, intact as well as provided with implants Comparable experiments were conducted by Oh and Harris (1978) who applied only a few strain gauges, but carried out measurements on different bones with different prostheses, by Huggler *et al* (1978) who also attached strain gauges to the prosthesis stem, and by McBeath *et al* (1979) As discussed in chapter 2, more of these experiments have been carried out specifically to verify theoretical results

The experiments conducted by our group concerned the cadaveric femur of a 52 yr-old man To the femur, kept in formaline, 112 rosette strain gauges were attached (fig 4 1 a) Forces on the head in 3 perpendicular directions and couples in 3 planes were applied

[illegible] as 20 000 N/mm and its Poisson s ratio as 0 37
Equivalent stresses were calculated using the maximal deformational energy criterion of Maxwell Huber Hencky Von Mises It should be noted that with such an experimental method the complete strain distribution in the structure can not be measured, but only the strain state at the outside surface The stresses, calculated from the experimental data, were compared to the corresponding values of stresses as calculated for the model, in this case σ_t, σ_z and $\tau_{zt} = \tau_{tz}$ at the outside surface of the bone
It was found that in loading by pure couples (up to 12 500 Nmm) the [illegible]

[illegible] after 3½ min of constant loading the strains stabilized to constant values. The reproduceability of the strain measurements was better than 5% even after 2½ years

The measurements were repeated for the same femur applied with [illegible] nails of three different diameters, hip endoprost[illegible] with short and long stems and osteo[illegible] study only [illegible] a long ceme[illegible] shown in fig [illegible] femur is influe[illegible] [illegible] stresses are considerably lower if a

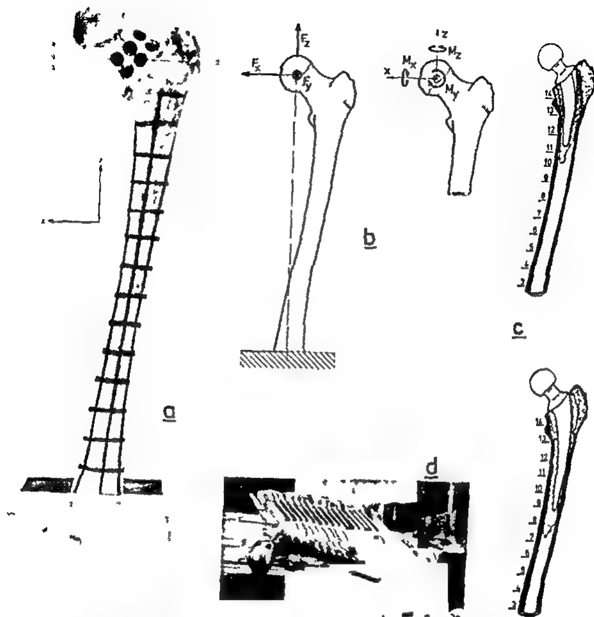

fig 4 1 Experimental stress analysis of a cadaveric femur Strain gauges were attached at the crossings of the black lines (a), forces in 3 directions and moments in 3 planes were applied to the head (b), measurements were performed on the intact femur as well as on the femur applied with hip prostheses (c), (d) shows the laboratory setting

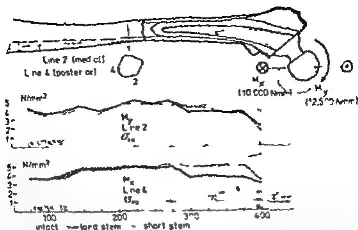
prosthesis stem is present because part of the loading is taken up by the stem According to Saint Venant's principle there is no influence on the distal side of the bone, hence the strains should be practically equal for the three cases in this region The graphs in fig 4 2 will later be compared with results of the model calculations

The experiments were carried out on the left femur of the cadaver, the right femur was used for detailed measurements of the cross sectional geometry (Laaper, 1973a)



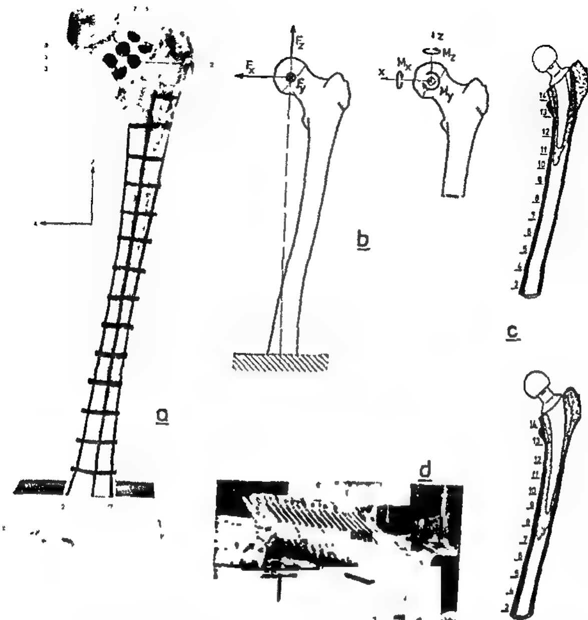


fig 4 2 Equivalent stresses at the outside surface of the femur, intact and with two endo prostheses of different lengths, loaded with two bending couples in different planes, respectively Top graph σ_{eq} on line 2 on loading with M_y, bottom graph σ_{eq} on line 4 on loading with M_x. The stresses were calculated from the measured strains, assuming homogeneity, isotropy and linear elasticity ($E = 20{,}000\ N/mm^2$, $\nu = 0.37$)

The data from these measurements were used for a three dimensional beam theory analysis of the femur (Laaper, 1973b v Heugten, 1975, Huiskes and Slooff, 1979b) A comparison of beam theory results and strain gauge results, principal stresses at different locations on loading with a couple in the frontal plane, is shown in fig 4 3

These results indicate that at least the intact femur behaves approximately in accordance with linear beam theory (which was also found by Scholten (1975) on comparing a beam analysis with a three dimensional FEM analysis (fig 2 1)), apart from the mentioned geometrical nonlinearity on loading with forces, especially in the z-direction

It should be remarked here that the Young s modulus is only used to calculate measured strains to stresses The agreement with the beam analysis thus indicates a good choice of the value of this parameter

It is remarkable, regarding figs 4 2 and 4 3, that although the femur s wider on the proximal side the strain values over the length of the bone are, roughly speaking, more-or less constant This indicates that the flexural stiffness of the bone would be fairly constant, due to the higher flexibility of the bone material (spongeous bone) at the proximal side

ig 4.1: Experimental stress analysis of a cadaveric femur. Strain gauges were attached at the crossings of the black lines (a); forces in 3 directions and moments in 3 planes were applied to the head (b); measurements were performed on the intact femur as well as on the femur applied with hip prostheses (c), (d) shows the laboratory setting.

rosthesis stem is present because part of the loading is taken up by the stem According to aint Venant's principle there is no influence on the distal side of the bone, hence the rains should be practically equal for the three cases in this region The graphs in fig 4 2 ill later be compared with results of the model calculations

he experiments were carried out on the left femur of the cadaver, the right femur was used or detailed measurements of the cross-sectional geometry (Laaper, 1973a)

CHAPTER FIVE

THEORETICAL STRESS ANALYSES

In this chapter a three-dimensional FEM analysis of the model presented in chapter 3 will be discussed The results of this analysis serve as references for the development of more simplified, analytical descriptions of the model that are better suited to characterize its mechanical behavior in principle

In paragraph 5 4 a FEM beam model of the structure will be presented This last model and the analytical models, too, are based on beams on-elastic foundation theory, in which it is assumed that the stem and the bone separately behave in accordance with linear beam theory, while the cement mantle serves as an elastic layer This in contradiction to composite beam theory, sometimes applied in the literature, in which it is assumed that the structure [illegible] an entity behaves according to beam theory

In the last paragraph of this chapter the possibilities and limitations of plane FEM analyses will be discussed

5 1 Three-dimensional FEM analysis

For the FEM analysis of the model an axisymmetric ring element is used, that can take nonaxisymmetric loading into account by expansion of loads, displacements, strains and stresses into Fourier series (Fourier element) The complete sol t on can be obt [illegible]

[illegible] degrees of freedom) as shown in fig 5 1 Also other elements and element meshes were applied [illegible] discussed in Huiskes *et al* (1977)

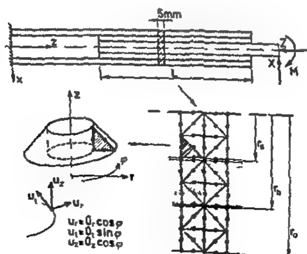

fig 5 1 Element mesh and ring element used in the three-dimensional FEM calculations

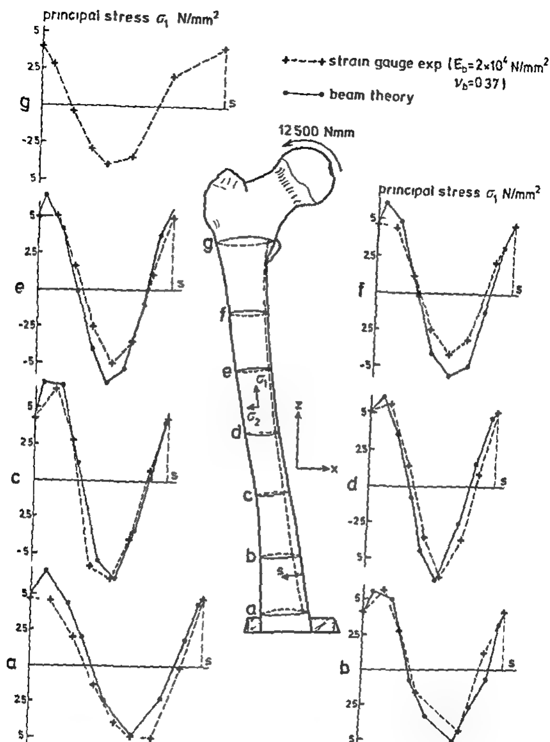

fig 4 3 Principal stresses (σ_1) on the outside of the femur, as calculated from strain-gauge measurements (left cadaveric femur) and as calculated with beam theory, using cross sectional geometry data The beam analysis did not extend further proximally than location f The principal stress direction is, with good approximation, in that of the femoral axis For the calculation of principal stresses from principal strains … ity was … values

The element used is triangular in cross section and has 6 nodal points In each element the stress amplitudes are linear in r and z

The calculations have been carried out using the FEM computer system FEMSYS (Banens, 1977) The accuracy of the results has been checked using analytical considerations (Huiskes, 1977)

Results

All stress component amplitudes in all nodal points were calculated for the three loading cases. From these amplitudes the stresses for any value of φ can be evaluated using the expressions shown in table 5 1 and the equivalent stress can be calculated using the formula presented in chapter 3 In the present work the stress distribution as a function of φ and r (presented in Huiskes, 1977, and Huiskes *et al*, 1977) will not be discussed As a rule, stress amplitudes as a function of z on four different lines will be presented in the stem (line 1) and in the cement (line 2) at the stem cement interface ($r = r_s$) and in the cement (line 3) and in the bone (line 4) at the cement-bone interface ($r = r_b$)

Fig. 5 3 gives an example of stress (σ_{eq}) as a function of z on the four lines just mentioned, resulting from the transverse force X A set of all relevant results for loading cases Z and X is shown in appendix A

When the results of the FEM calculations are compared with those of the experimental stress analysis of the cadaveric femur with implants, discussed in chapter 4, no detailed agreement can be expected owing to the simplified character of the model

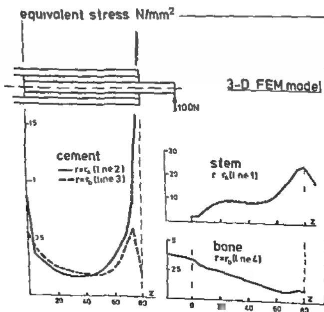

fig 5 3 Equivalent stresses in the stem (at line 1), the bone (at line 4) and the cement (at lines 2 and 3) as functions of z, for a transverse force of 100 N on the stem

The loads (Z, X and M) are expanded into Fourier series, but only the first term of each series is used Hence, the loads are assumed to be distributed along a nodal ring (fig 5 2) and Z, X and M are the respective resultants of these distributions This greatly economizes the solution procedure, while the effects of the assumed loading on the structure are equal to those of concentrated loading, thanks to the relatively large free stem length to which Saint Venant's principle applies

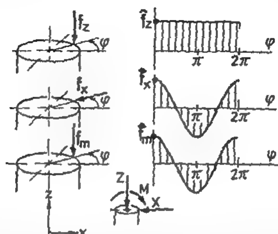

fig 5 2 The forces and the moment on the stem are assumed to be distributed along a nodal ring, either as constant or as sine or cosine functions in φ $f_z = \hat{f}_z$, $f_x = \hat{f}_x\cos\varphi$ and $f_m = \hat{f}_m\cos\varphi$, the resultants of which are Z, X and M, respectively

In consequence of this method the stresses, strains and displacements that result from the axial loading (Z) are constant in φ and those that result from the transverse loading (X and M) are sine or cosine functions in φ For the stresses these functions are summarized in table 5 1

The quantities $\hat{\sigma}_r$, $\hat{\sigma}_t$, $\hat{\tau}_{rt}$ etc will be referred to as stress 'amplitudes , it should be borne in mind that the term in this case does not refer to dynamic loading It is evident that the stress amplitude values are equal to the maximum stress values on a nodal ring, for τ_{rt} and τ_{tz} at $\varphi = \pi/2$, for the other components at $\varphi = 0$

stress component		axial loading (Z)	transverse loading (X M)
radial stress	σ_r	$\sigma_r(r,z)$	$\hat{\sigma}_r(r,z)\cos\varphi$
hoop stress	σ_t	$\sigma_t(r,z)$	$\hat{\sigma}_t(r,z)\cos\varphi$
axial stress	σ_z	$\sigma_z(r z)$	$\hat{\sigma}_z(r,z)\cos\varphi$
circumferential shear stress	τ_{rt}	0	$\hat{\tau}_{rt}(r,z)\sin\varphi$
longitudinal shear stress	τ_{rz}	$\tau_{rz}(r z)$	$\hat{\tau}_{rz}(r z)\cos\varphi$
transverse shear stress	τ_{tz}	0	$\hat{\tau}_{tz}(r,z)\sin\varphi$

table 5 1 Expressions for the six stress components in axial and in transverse loading

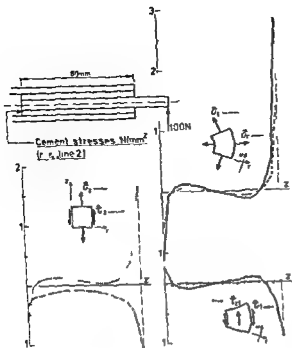

fig 5 6 Stresses in the cement at the stem-cement interface on loading with a transverse force Apart from τ_{zt} the components are of comparable magnitude, indicating that the stress state in the cement is truly three-dimensional, σ_r shows the highest value

- The stress state in the cement is truly three-dimensional, which means that the stress components have comparable magnitudes (fig 5 6) The highest stresses in the cement occur near the stem cement interface, on the proximal and distal sides, for all stress components and for all loading cases Of the six components, σ_r shows the highest values at these locations.
  If σ_{eq} is used as a criterion for the stress state, then σ_r gives a good indication of its maximum value and τ_{rz} gives a good indication of its course as a function of z
  Although the stress distributions differ for the transverse force and the bending moment, the results in principle give the same kind of information, hence, for a principle characterization it would be sufficient to consider only one of these loading cases Here the transverse force was chosen as the representative loading case
- As mentioned in chapter 3 the stres
  across the inte
  requirement v

  centrations at bo
  decrease sharply
  inadequately ref ... element mesh in these regions
  To describe this end-effect (that also occurs in so called 'shear lag' problems, e g Timoshenko and Goodier, 1970) a very refined mesh would be needed
  The stress values found for τ_{rz} at the ends are assumed to be reasonable *representations*

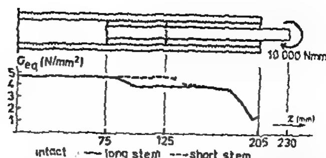

fig 5 4 Equivalent stresses at the outside surface of the bone cylinder, for two different stem lengths (80 and 130 mm) and the bone without stem, on loading with a pu couple To be compared with experimental results shown in fig 4 2

A qualitative agreement was clearly established, however, as is illustrated in fig 5 4, show equivalent stresses on the outside surface of the bone cylinder as calculated for the intac case and with implants of two different lengths on loading with a bending moment Comparison of these graphs with fig 4 2 makes it apparent that the model results and the experimental results agree in the qualitative sense

As regards the calculated stress distribution in general the following conclusions can be reached

- Relative to the axial stress (σ_z) all other stress components in the stem have insignifica values for all loads Hence, the equivalent stress is practically equal to the axial stress This indicates also that the stem behaves in accordance with beam theory, which is hardly surprising
- This is also true, although to a lesser extent, for the bone On the proximal side stress components other than the axial one have significant values also This means that, apar from the proximal side, the equivalent stress is almost equal to σ_z as shown in fig 5 5

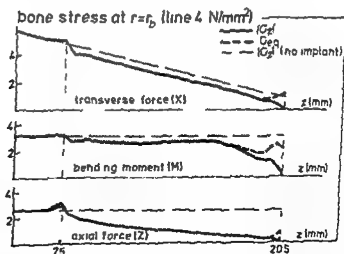

fig 5 5 Axial stress (σ_z) and equivalent stress (σ_{eq}) in the bone at line 4 ($r = r_b$) as functions of z, for three loading cases Only on the proximal side do they differ The natural axial stress for the bone without implant is also shown Especially th axial force results in low stress values as compared with the intact bone (stem lengt 130 mm)

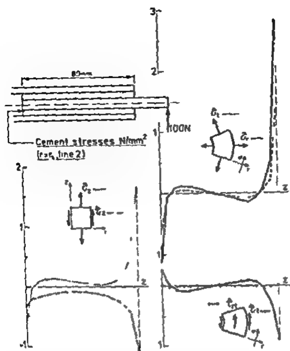

fig 5 6 Stresses in the cement at the stem-cement interface on loading with a transverse force Apart from τ_{zt} the components are of comparable magnitude, indicating that the stress state in the cement is truly three-dimensional, σ_r shows the highest value

- The stress state in the cement is truly three-dimensional, which means that the stress components have comparable magnitudes (fig 5 6) The highest stresses in the cement occur near the stem cement interface, on the proximal and distal sides, for all stress components and for all loading cases Of the six components, σ_r shows the highest values at these locations

  If σ_{eq} is used as a criterion for the stress state, then σ_r gives a good indication of its maximum value and τ_{rz} gives a good indication of its course as a function of z Although the stress distributions differ for the transverse force and the bending moment, the results in principle give the same kind of information, hence, for a principle characterization it would be sufficient to consider only one of these loading cases Here the transverse force was chosen as the representative loading case
- As mentioned in chapter 3, the stress components σ_r, τ_{rt} and τ_{rz} have to be continuous across the interface due to the action = reaction law In the calculated results this requirement was fulfilled with quite reasonable accuracy (Huiskes, 1977)
- As is shown, for instance in fig 5 6, the cement stress components show high stress concentrations at both ends Where τ_{rz} is concerned, the stress should, after a steep rise, decrease sharply to zero at the ends That this is not described by the model is due to an inadequately refined element mesh in these regions.

  To describe this end-effect (that also occurs in so called 'shear lag' problems, e g Timoshenko and Goodier, 1970) a very refined mesh would be needed

  The stress values found for τ_{rz} at the ends are assumed to be reasonable representations

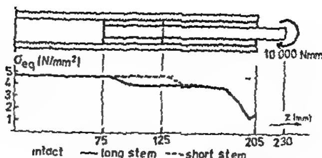

fig 5 4 Equivalent stresses at the outside surface of the bone cylinder, for two different stem lengths (80 and 130 mm) and the bone without stem, on loading with a pure couple. To be compared with experimental results shown in fig 4 2

A qualitative agreement was clearly established, however, as is illustrated in fig 5 4, showing equivalent stresses on the outside surface of the bone cylinder as calculated for the 'intact' case and with implants of two different lengths on loading with a bending moment Comparison of these graphs with fig 4 2 makes it apparent that the model results and the experimental results agree in the qualitative sense

As regards the calculated stress distribution in general the following conclusions can be reached

- *Relative to the axial stress (σ_z) all other stress components in the stem have insignificant* values for all loads Hence, the equivalent stress is practically equal to the axial stress This indicates also that the stem behaves in accordance with beam theory, which is hardly surprising
- This is also true, although to a lesser extent, for the bone On the proximal side stress components other than the axial one have significant values also This means that, apart from the proximal side, the equivalent stress is almost equal to σ_z, as shown in fig 5 5

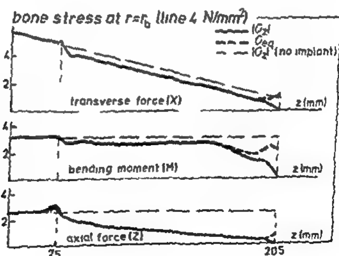

fig 5 5 [illegible] *axial force results in low stress values as compared with the intact bone (stem length 130 mm)*

5 2. Beams-on-elastic foundation theory

As will be shown in this paragraph, the mechanical behavior of the model can be approximated by applying beams-on-elastic foundation theory, for transverse as well as for axial loading. Both cases will be treated separately

5 2 1 *Transverse loading*

The theory of beams-on-elastic-foundation has been described in depth by Hetényi (1946). The difference in this case from the usual one, is caused by the circumstance that both beams (the stem and the bone) make a contribution to each other's elastic foundation. It is assumed that both the stem and the bone behave in accordance with beam theory. The resistance of the intermediate layer (the cement mantle) to shear and axial loading is neglected in this case and its transverse stiffness is taken into account by assuming a continuous set of linear springs (Winkler hypothesis, Hetenyi, 1946)

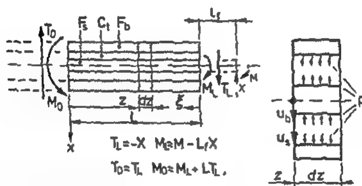

fig 5 8 Parameters and variables of the beams-on-elastic foundation model for transverse loading. The external loads in this model can easily be calculated from the previously defined loading system (M and X), as shown in the figure

The parameters of the model are shown in fig 5 8. The transverse stiffness of the elastic layer C_t (N/mm^2) is defined by

$$p = C_t(u_s - u_b) \tag{5 1}$$

where $u_s(z)$ and $u_b(z)$ are the deflections of the stem and the bone neutral axes respectively, and $p(z)$ (N/mm) is the continuously distributed transverse load that the cement exerts on the stem and vice versa and that the cement exerts on the bone and vice versa.
As follows directly from beam theory

$$F_s \frac{d^4 u_s}{dz^4} + p = 0 \quad \text{and} \quad F_b \frac{d^4 u_b}{dz^4} - p = 0 \tag{5 2}$$

of the maximal values that will in reality occur somewhat away from the ends In this respect shear stress measurements were carried out by Stern (1977) in an axisymmetric structure consisting of an aluminium tube and a steel rod with acrylic cement in between, under axial loading, using optic stress films He found the same kind of curves as calcu lated with the model

It is apparent when looking at the stress distribution in the structure (figs 5 3 through 5 6 and appendix A), that the fixation system can be divided into three regions (fig 5 7) a *middle region*, where the structure behaves as a composite beam, which means that the stem and the bone each take a part of the total load depending on the ratio of their flexural and compressional stiffness, a proximal region, where the load is passed from the stem to the bone, and a distal region where, looking from the other side, the load is passed from the bone to the stem As will be shown in paragraph 5 3, these regions can be treated separately and approximative formulas can be derived to describe the most important stress components in these regions as functions of the structural parameters These approximations are based on beams on elastic foundation theory, that will be discussed in paragraph 5 2

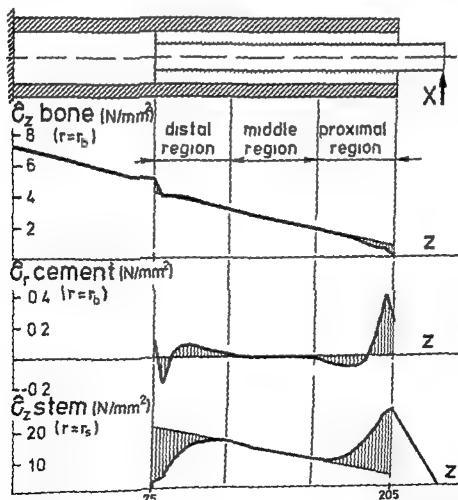

fig 5 7 With respect to its mechanical behavior, the intramedullary fixation system can be divided into three regions The middle region behaves in accordance with com ... s te beam theory Deviations from composite beam theory in the proximal and ... and the stem, and

Since

$$\lambda_t = \sqrt[4]{\left(\frac{C_t}{4F_s}\left(1 + \frac{F_s}{F_b}\right)\right)}$$

it follows that when $F_s \ll F_b$, the bone can be assumed to be rigid

If circular geometry is assumed, as in the model described in chapter 3, it follows (see also appendix B), that

$$F_s = \frac{\pi}{4}E_s r_s^4, \quad F_b = \frac{\pi}{4}E_b(r_o^4 - r_b^4), \quad C_t = c_1 E_c g(\nu_c)\left(c_2 + \frac{\rho}{1-\rho}\right),$$

where c_1, c_2 constants depending on the interface conditions and
$g(\nu_c)$ expression in ν_c, to be evaluated graphically,
$\rho = r_s/r_b$

In this case the continuously distributed transverse load $p(z)$ is the resultant of the stress components σ_r and τ_{rt}, as shown in fig 5 9

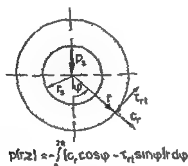

fig 5 9 Definition of the continuously distributed transverse load $p(r,z)$ in a circular cross section, $p_s(z) = p(r_s,z)$ and $p_b(z) = p(r_b,z)$ In the beams-on-elastic foundation theory $p(r,z) = p(z)$, hence $p_s = p_b = p$

A comparison of results (M_s M_b and p as functions of z) as calculated with the FEM model and with the method presented in this paragraph, is shown in fig 5 10 The agreement in M_s and M_b is good, the agreement in p is reasonable

The variables $M_s(z)$ and $M_b(z)$ can be calculated directly to axial stem and bone stresses (σ_z) the maximal values of which are denoted by $s_{zs}(z)$ and $s_{zb}(z)$, respectively, as

$$s_{zs} = \frac{M_s}{W_s} \quad \text{and} \quad s_{zb} = \frac{M_b}{W_b} \qquad (5\ 7)$$

The transverse load $p(z)$ cannot be calculated to stresses, since it depends on both σ_r and τ_{rt} (fig 5 9) Representative average stress variables $\xi_{rs}(z)$ and $\xi_{rb}(z)$ are introduced as

where F_s and F_b denote the flexural stiffness of the stem and the bone, respectively ($F = EI$)

Equations (5 1) and (5 2) can be solved to give

$$u_s(z) = e^{\lambda_t z} D_1(z) + e^{\lambda_t z} D_2(z) + \sum_{i=0}^{3} a_i z^i \tag{5 3}$$

$$u_b(z) = -\frac{F_s}{F_b} e^{\lambda_t z} D_1(z) + \frac{F_s}{F_b} e^{\lambda_t z} D_2(z) + \sum_{i=0}^{3} a_i z^i \tag{5 4}$$

$$p(z) = C_t\left(1 + \frac{F_s}{F_b}\right)\left(e^{\lambda_t z} D_1(z) + e^{\lambda_t z} D_2(z)\right) \tag{5 5}$$

where

$D_1 = A_1 \cos\lambda_t z + A_2 \sin\lambda_t z$

$D_2 = A_3 \cos\lambda_t z + A_4 \sin\lambda_t z$

$\lambda_t = \sqrt[4]{\left\{\frac{C_t}{4}\left(\frac{1}{F_s} + \frac{1}{F_b}\right)\right\}}$

by using the boundary conditions

$$u_b(0) = 0,\quad \frac{du_b}{dz}(0) = 0,\quad \frac{d^2u_b}{dz^2}(L) = 0,\quad \frac{d^3u_b}{dz^3}(L) = 0,\quad \frac{d^2u_s}{dz^2}(0) = 0,\quad \frac{d^3u_s}{dz^3}(0) = 0,$$

$$\frac{d^2u_s}{dz^2}(L) = \frac{M_L}{F_s},\quad \frac{d^3u_s}{dz^3}(L) = -\frac{T_L}{F_s}\ ,$$

the constants A_1 through A_4 and a_0 through a_3 can be calculated which gives u_s u_b and p The bending moments in the stem and bone follow from

$$M_s(z) = F_s \frac{d^2u_s}{dz^2} \quad \text{and} \quad M_b(z) = F_b \frac{d^2u_b}{dz^2} \tag{5 6}$$

For these calculations a computer program was set up

The parameters that determine the mechanical behavior of the structure described by $M_s(z)$, $M_b(z)$ and $p(z)$, are C_t, F_s, F_b and L The formulas presented above are valid for arbitrary (constant) cross sectional geometry of the stem and the bone, where C_t can be approximated by the formulas given in appendix B
As follows from formulas (5 3), (5 4) and (5 5) the mechanical behavior of the structure is principally characterized by the parameter λ_t

fig 5.11 Parameters and variables of the beams-on-elastic foundation model for transverse loading. The axial load N_L is directed opposite to the previously defined load Z

$$P_s \frac{d^2 w_s}{dz^2} + q = 0 \quad \text{and} \quad P_b \frac{d^2 w_b}{dz^2} - q = 0 \qquad (5.10)$$

where P_s and P_b are the compressional stiffness of stem and bone respectively ($P = EA$)

Equations (5.9) and (5.10) can be solved to give

$$w_s(z) = A_1 e^{\lambda_a z} + A_2 e^{\lambda_a z} + A_3 + A_4 z \qquad (5.11)$$

$$w_b(z) = -\frac{P_s}{P_b} A_1 e^{\lambda_a z} - \frac{P_s}{P_b} A_2 e^{\lambda_a z} + A_3 + A_4 z \qquad (5.12)$$

$$q(z) = -C_a\left(1 + \frac{P_s}{P_b}\right)\left(A_1 e^{\lambda_a z} + A_2 e^{\lambda_a z}\right) \qquad (5.13)$$

where

$$\lambda_a = \sqrt{\left\{C_a\left(\frac{1}{P_s} + \frac{1}{P_b}\right)\right\}}$$

Using the boundary conditions

$$w_b(0) = 0, \quad \frac{dw_b}{dz}(L) = 0, \quad \frac{dw_s}{dz}(0) = 0, \quad \frac{dw_s}{dz}(L) = \frac{N_L}{P_s},$$

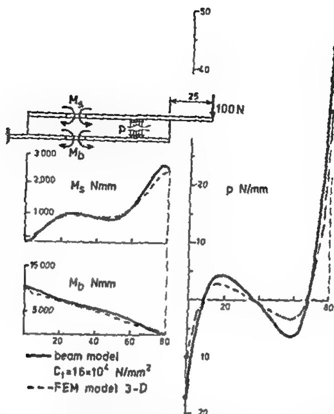

fig 5.10 Comparison of the bending moments in the stem (M_s) and the bone (M_b), and the continuously distributed transverse load (p), as calculated with the FEM model and with the beams on elastic foundation theory. The curve for p(z) in the case of the FEM model is taken as $p = (p_s + p_b) / 2$, in the analytical model $p_s = p_b = p$

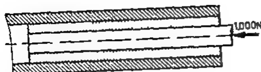
$$\xi_{rs} = \frac{p}{2r_s} \quad \text{and} \quad \xi_{rb} = \frac{p}{2r_b} \tag{5 8}$$



5 2 2 *Axial loading*

For axial loading the same strategy is followed as for transverse loading It is again assumed that both the stem and the bone behave in accordance with beam theory The resistance of the cement mantle to transverse loading and axial loading is neglected in this case and its axial shearing stiffness is represented by a continuous set of linear springs
The parameters of the model are shown in fig 5 11
The shearing stiffness of the cement layer C_a (N/mm²) for axial loading is defined as

$$q = C_a(w_b - w_s) \tag{5 9}$$

where $w_b(z)$ and $w_s(z)$ are the displacements in the axial direction of the bone and the stem, respectively, and $q(z)$ (N/mm) is the continuously distributed axial shearing load that the cement exerts on the stem and the bone and vice versa

As follows directly from beam theory (or bar theory),

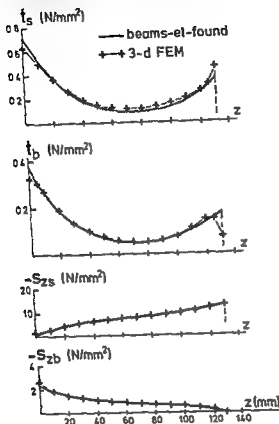


fig 5 12

beams-on elastic foundation model

As already discussed in paragraph 5 1 the shear stress at the interfaces at both ends, after the steep rise, should decrease sharply to zero In this case, too, the model does not describe this phenomenon The calculated values for t_s and t_b at the ends should be regarded as representing maximal values that occur a little distance away from these ends in reality

5 3 Approximative formulas

As we have seen in paragraph 5 1, the fixation system can be divided into three regions where its mechanical behavior is concerned This can easily be understood if the structure is assumed to be of semi infinite length (fig 5 13)

the constants A_1 through A_4 can be calculated, which gives w_s, w_b and q

The axial loads in stem and bone follow from

$$N_s(z) = P_s \frac{dw_s}{dz} \quad \text{and} \quad N_b(z) = P_b \frac{dw_b}{dz} \qquad (5\ 14)$$

The parameters that determine the mechanical behavior of the structure described by $N_s(z)$, $N_b(z)$ and $q(z)$, are C_a, P_s, P_b and L, and the formulas presented are again valid for arbitrary (constant) cross sectional geometry of the stem and the bone, where C_a can be approximated by the formulas given in appendix B In the axial loading case, too, it follows since

$$\lambda_a = \sqrt{\left\{\frac{C_a}{P_s}\left(1 + \frac{P_s}{P_b}\right)\right\}}$$

that if $P_s \ll P_b$, the bone can be assumed to be rigid

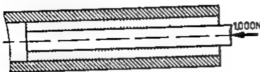
For circular geometry, as in the model described in chapter 3, it follows (see also appendix B), that

$$P_s = \pi E_s r_s^2, \quad P_b = \pi E_b (r_o^2 - r_b^2), \quad C_a = -\frac{\pi E_c}{(1 + \nu_c)\ln\rho}$$

In this case the continuously distributed axial shearing load $q(z)$ is the resultant of the axial shear stress τ_{rz} In general

$$q(r,z) = \int_0^{2\pi} \tau_{rz}(r,z) r d\varphi, \qquad (5\ 15)$$

if we define $t_s(z) = \tau_{rz}(r_s,z)$ and $t_b(z) = \tau_{rz}(r_b,z)$, it follows that



$$q_s(z) = t_s \gamma_s \quad \text{and} \quad q_b(z) = t_b \gamma_b, \qquad (5\ 16)$$

where γ_s and γ_b (mm) are the outer stem and the inner bone circumferences respectively Due to the assumptions in the beams on elastic foundation theory, $q_s = q_b = q$

The axial stress in the stem and the bone denoted by $s_{zs}(z)$ and $s_{zb}(z)$, respectively, follow from

$$s_{zs} = \frac{N_s}{A_s} \quad \text{and} \quad s_{zb} = \frac{N_b}{A_b} \qquad (5\ 17)$$

Fig 5 ... lated with
the FE...
ment is good

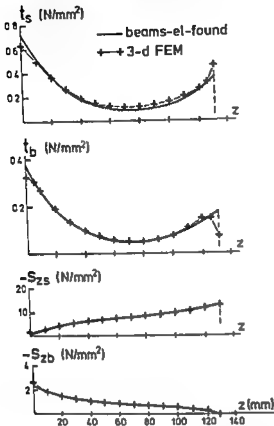


fig 5.12 Comparison of axial stem stress (s_{zs}), bone stress (s_{zb}), stem-cement interface shear stress (t_s) and bone-cement interface shear stress (t_b) upon axial loading (N_L = -1000N) as calculated with the FEM model and as calculated with the beams-on-elastic foundation model

As already discussed in paragraph 5.1 the shear stress at the interfaces at both ends, after the steep rise, should decrease sharply to zero. In this case, too, the model does not describe this phenomenon. The calculated values for t_s and t_b at the ends should be regarded as representing maximal values that occur a little distance away from these ends in reality.

5.3 Approximative formulas

As we have seen in paragraph 5.1, the fixation system can be divided into three regions where its mechanical behavior is concerned. This can easily be understood if the structure is assumed to be of semi infinite length (fig. 5.13)

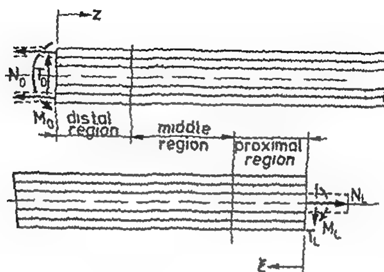

fig 5 13 On assuming the structure to be of semi infinite length, the proximal and distal regions are treated separately The loading systems for these two cases are shown

The solutions of the differential equations for axial and transverse loading, (5 3) through (5 5) and (5 11) through (5 13), are again valid, also the boundary conditions for $z = 0$ remain unchanged, but the boundary conditions for $z = L$ have to be replaced by require ments of vanishing initial effects for $z \to \infty$, hence $D_1 = 0$ in formulas (5 3) through (5 5) and $A_1 = 0$ in formulas (5 11) through (5 13) After establishing the constants, using the remaining boundary conditions at $z = 0$, it follows for transverse loading at the distal side that

$$M_s(z) = \frac{F_s}{F_s+F_b}\left\{M_0 - T_0 z - e^{\lambda_t z}\left(M_0 \cos\lambda_t z + \left(M_0 - \frac{T_0}{\lambda_t}\right)\sin\lambda_t z\right)\right\} \tag{5 18}$$

$$M_b(z) = \frac{F_s}{F_s+F_b}\left\{\frac{F_b}{F_s}M_0 - \frac{F_b}{F_s}T_0 z + e^{\lambda_t z}\left(M_0 \cos\lambda_t z + \left(M_0 - \frac{T_0}{\lambda_t}\right)\sin\lambda_t z\right)\right\} \tag{5 19}$$

$$p(z) = \frac{1}{2}\frac{C_t}{\lambda_t^2 F_b}\, e^{\lambda_t z}\left(M_0 \sin\lambda_t z - \left(M_0 - \frac{T_0}{\lambda_t}\right)\cos\lambda_t z\right) \tag{5 20}$$

and for axial loading that

$$N_s(z) = \frac{P_s}{P_s+P_b}N_0\left(1 - e^{\lambda_a z}\right), \quad N_b(z) = \frac{P_b}{P_s+P_b}N_0\left(1 + \frac{P_s}{P_b}e^{\lambda_a z}\right) \tag{5 21}$$

$$q(z) = -\frac{\lambda_a P_s}{P_s + P_b} N_0 e^{\lambda_a z} \quad (5\ 22)$$

The same kind of formulas can be established for the other (proximal) side, replacing z by ξ, F_s by F_b, P_s by P_b, M_0 by M_L, T_0 by T_L and N_0 by N_L
On both sides separately the system has a force introduction region the length of which is determined by $e^{\lambda_t z}$ and $e^{\lambda_a z}$, hence by λ_t and λ_a For higher z the expressions for the loading variables reduce to

$$M_s(z) = \frac{F_s}{F_s + F_b}(M_0 - T_0 z), \quad M_b(z) = \frac{F_b}{F_s + F_b}(M_0 - T_0 z), \quad p(z) = 0, \quad (5\ 23)$$

$$N_s(z) = \frac{P_s}{P_s + P_b} N_0 \quad N_b(z) = \frac{P_b}{P_s + P_b} N_0, \quad q(z) = 0 \quad (5\ 24)$$

the well known formulas for composite beam theory, applying to an infinitely long composite structure (e g. Muskhelshvili, 1963, Bartel and Desormeaux, 1976a) In this case the flexural and compressional stiffness of the cement layer is neglected, allowed since $F_c \ll F_s + F_b$ and $P_c \ll P_s + P_b$
Whether or not these formulas apply to the middle region or, in other words, whether or not there is a middle region, depends on the stem length and the values of λ_a and λ_t For transverse loading the traditional criterion for beams-on elastic foundation theory can be used (Hetenyi 1946)

$\lambda_t L \leq \frac{\pi}{4}$	short beam, both the stem and the bone can be assumed as rigid to find a good approximation of p(z)
$\frac{\pi}{4} < \lambda_t L < \pi$	intermediate beam length, both sides of the system influence each other, the full theory has to be used, composite beam theory is not appropriate for any section
$\lambda_t L \geq \pi$	long beam the behavior of the proximal and distal ends are independent by approximation and the structure can be analyzed by analyzing the proximal region, the middle region and the distal region separately

Th λ

When the same criterion is used for axial loading for λ_a, it follows for $\lambda_a L = \pi$, $e^{\lambda_a L/2} \approx 0\ 2$, hence 80% of the *initial effect would have* vanished at half the stem length, so there would still be a *significant* interaction between both sides For $\lambda_a L \approx 4\ 6$, 90% of the effect would have vanished and 95% for $\lambda_a L \approx 6\ 0$

Fig 5 15 shows a comparison of results *for p(z)* and q(z) as calculated using the beams on elastic foundation theory presented in *paragraph 5 2 and* using the sem of ... xi
mation for both side ...
The semi ... de)
load ng b ... xial
$\lambda_a L \approx 2$ ...
... ue the approximation of q(z) is not bad

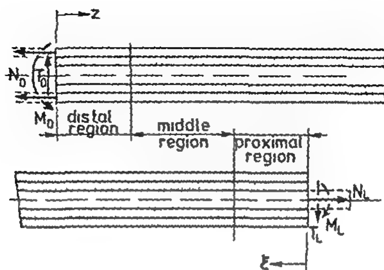

fig 5 13 On assuming the structure to be of semi infinite length, the proximal and distal regions are treated separately The loading systems for these two cases are shown

The solutions of the differential equations for axial and transverse loading, (5 3) through (5 5) and (5 11) through (5 13), are again valid, also the boundary conditions for $z = 0$ remain unchanged, but the boundary conditions for $z = L$ have to be replaced by requirements of vanishing initial effects for $z \rightarrow \infty$, hence $D_1 = 0$ in formulas (5 3) through (5 5) and $A_1 = 0$ in formulas (5 11) through (5 13) After establishing the constants, using the remaining boundary conditions at $z = 0$, it follows for transverse loading at the distal side that

$$M_s(z) = \frac{F_s}{F_s+F_b}\left\{M_0 - T_0 z - e^{\lambda_t z}\left(M_0 \cos\lambda_t z + (M_0 - \frac{T_0}{\lambda_t})\sin\lambda_t z\right)\right\} \tag{5 18}$$

$$M_b(z) = \frac{F_s}{F_s+F_b}\left\{\frac{F_b}{F_s}M_0 - \frac{F_b}{F_s}T_0 z + e^{\lambda_t z}\left(M_0 \cos\lambda_t z + (M_0 - \frac{T_0}{\lambda_t})\sin\lambda_t z\right)\right\} \tag{5 19}$$

$$p(z) = \frac{1}{2}\frac{C_t}{\lambda_t^2 F_b} e^{\lambda_t z}\left(M_0 \sin\lambda_t z - (M_0 - \frac{T_0}{\lambda_t})\cos\lambda_t z\right) \tag{5 20}$$

and for axial loading that

$$N_s(z) = \frac{P_s}{P_s+P_b} N_0 (1 - e^{\lambda_a z}), \quad N_b(z) = \frac{P_b}{P_s+P_b} N_0 (1 + \frac{P_s}{P_b} e^{\lambda_a z}) \tag{5 21}$$

When $\lambda_t L \gtrsim \pi$ and $\lambda_a L \gtrsim \pi$ the structure can be divided into a proximal, a middle and a distal region, in which the most important stress components can be calculated using simple formulas, as summarized in table 5 II From these formulas, the stresses in the stem and the bone (s_{zs} and s_{zb}) and the normal and shear stresses at the interfaces (s_{rs}, s_{rb}, t_s and t_b) can be calculated for given geometry

		Transverse loading (M_L and T_L)	Axial loading (N_L)

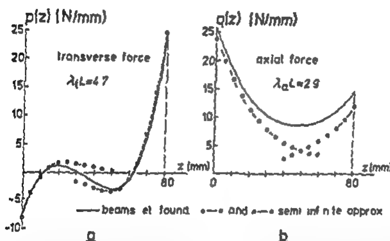

fig 5 15 A comparison of results for p(z) (a) and q(z) (b) as calculated for a structure of finite length and as calculated assuming semi infinite length on both sides, respectively

Summarizing, it can be said that the application of the approximative semi infinite beams on elastic foundation theory gives excellent opportunities to characterize the mechanical behavior of the intramedullary bone prosthesis structure and to develop a fundamental, general concept on the relations between stresses and the most important structural parameters

A first characterization follows from the quantities $\lambda_t L$ and $\lambda_a L$, where

$$\lambda_t = \sqrt[4]{\left\{\frac{C_t}{4}\left(\frac{1}{F_s} + \frac{1}{F_b}\right)\right\}} \quad \text{and} \quad \lambda_a = \sqrt{\left\{C_a\left(\frac{1}{P_s} + \frac{1}{P_b}\right)\right\}},$$

and C_t and C_a can be evaluated using the formulas presented in appendix B

tem

behavior so much in general, but do influence the local stress values These parameters, too, should be represented adequately in the model

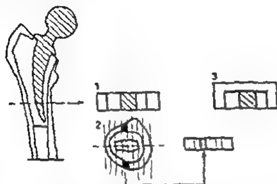

fig 5 17 Three different methods of representing the hip endoprosthesis fixation system in a plane model 1 as it appears in a longitudinal section, 2 using composite materials theory to take the out-of plane material stiffness into account (see also fig 5 18), 3 using side plates (a 'spanning element' layer) to take the medial lateral cortex connection into account

Three different method of mod

(fig 5 17)

structure

1975 Kwak *et al*, 1979) In this case no connection exists in the model between the lateral and the medial cortex Hence, apart from the question whether this model can take the correct parameter values of the system into account, the model in essence consists of three beams connected by two elastic layers Since the elastic lines (or neutral axes) of these beams do not coincide, a sandwich construction results, in which the stiffness is to a great extent determined by shear at the cement bone interfaces (e g Girkman, 1963) which is a quite unrealistic representation of the structure

A second method is the one in which the theory of compos

McNeice *et al*, 1975, 1976)

the stiffness of the out-of pl

of an effective thickness (t_e) and Young s modulus (E_e) for every plane element, as shown in fig 5 18

$$E_1 E_2 \; E_3 \; E_4 E_5 \rightarrow E_e \quad t_e E_e = \sum_{i=1}^{5} t_i E_i$$

fig 5 18 In using the composite materials theory, the out-of-plane stiffness of the structure consisting in this case, of three materials, is represented by a plane element whose stiffness characteristics are calculated from the three original materials, taking into account their thickness and Young s moduli

variations in the elastic moduli of the three materials in order to investigate influences of incomplete cement mantles and bone resorption Spongeous bone layers of varying thickness too, can be taken into account in such a model
In this model the stem and the bone are represented by a number of beam elements and the cement mantle by special spring elements that simulate the stiffness of the layer in the axial and transverse directions (C_a and C_t), as shown in fig 5 16 In the model, the quantities $M_s(z)$, $M_b(z)$, $N_s(z)$, $N_b(z)$, $q(z)$, $p(z)$, $s_{zs}(z)$, $s_{zb}(z)$, $\bar{s}_{rs}(z)$, $\bar{s}_{rb}(z)$, $t_s(z)$ and $t_b(z)$ are calculated just as with the model described in paragraph 5 2 On comparison of results from both models, the agreement was found to be excellent

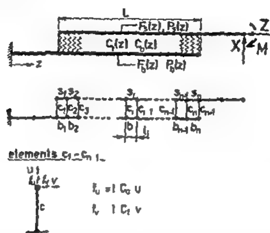

fig 5 16 Characterization of the FEM beam model, the elements s_i and b_i are beam elements representing the stem and the bone, respectively The cement mantle is represented by 'spring elements' (c_i), with certain stiffness characteristics in axial and transverse directions

This model can easily be extended to three dimensional geometry and a more sophisticated (three dimensional) representation of the cement mantle The restriction of this model is the requirement that the bone and the stem separately should behave in accordance with beam theory

5 5 Two dimensional (plane) FEM analysis

It is the object of this paragraph to discuss the possibilities and limitations of two dimensional FEM analyses rather than present results of such a model Although a two-dimensional FEM analysis of the simplified model presented in chapter 3 was carried out and will be used in chapter 6 it was apparent that the relation between the results of the three dimensional model and those of the two-dimensional model was rather confusing Many two [illegible] 2, and it [illegible] the previously developed concepts

Obviously, the modeling has to be carried out in such a way that the essential characteristics of the structure are represented in the model As was shown in the previous paragraphs, the essential parameters of the intramedullary bone prosthesis structure are λ_t, λ_a, F_s, F_b, P_b, P_s,

rameter		circular geometry	rectangular geometry

λ_a^2	(2)	$-\frac{E_c}{E_s}\frac{1}{(1+\nu_c)\ln\rho}\frac{1}{r_s^2}$	$\frac{E_c}{E_s}\frac{1}{2r_s(r_b-r_s)(1+\nu_c)}$
λ_t^4	(2)	$\frac{E_c}{E_s}\frac{4\rho(1-\nu_c)}{(1-\rho)(1+\nu_c)(1-2\nu_c)}\frac{1}{\pi r_s^4}$	$\frac{3}{4}\frac{E_c}{E_s}\frac{1-\nu_c}{(r_b-r_s)(1+\nu_c)(1-2\nu_c)}\frac{1}{r_s^3}$

table 5 III Formulas describing the characteristic parameters in an axisymmetric structure and in a two-dimensional (plane) model (see fig 5 19). (1) rough approximation, see appendix II (2) to make a first-order' general comparison possible $\lambda_a^2 \approx C_a/P_s$ and $\lambda_t^4 \approx C_t/4F_s$ are taken

In conclusion it is evident that unless axial and transverse loading are investigated with two [illegible]

worthless in this case when side plates are applied and care is taken to choose the dimensions in such a way as to meet the above mentioned requirements as fully as possible, tendencies could certainly be investigated in a relative sense But these two-dimensional models certainly do not have the accuracy that the visual apparent agreements between the models and the real structure suggest. Furthermore a comparison of results of different two dimensional models is difficult.

Apart from the fact that in this case, too, a sandwich construction results, the essential characteristics of the structure are not modeled correctly, because those elements that represent the stem also incorporate the stiffness of a piece of cement and a piece of bone and those elements that represent the cement incorporate part of the bone. What is modeled correctly in using this method is the overall stiffness of the full cross section. McNeice *et al* (1975) show in their results that the stresses in the stem increase by a factor of three if loosening occurs at the stem cement interface. This is exactly what would happen in a *sandwich construction, as they in fact analyzed, but not in the real structure, where the* lateral and medial cortex are connected, as will be shown in the next chapter.
A third method of modeling is the one in which the connection between the lateral and medial cortex of the bone is taken into account by applying a side plate or a 'spanning-element' layer in the model (fig. 5.17.3, e.g. Hampton *et al*, 1976, Svensson *et al*, 1977). This method is the only one that gives the option of modeling the system as a two beam structure in a plane and hence the only one that is suitable. However, it is questionable whether even in using this method the essential parameters mentioned previously can be adequately represented.

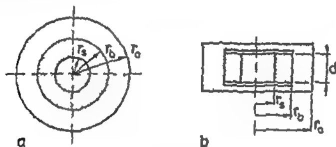

fig. 5.19 A plane representation (b) of a structure with axisymmetric cross section (a), applying side plates

As an example, a system with circular cross section is assumed (fig. 5.19 a). This structure has to be represented in a plane model, taking a 'spanning-element' layer into account (fig. 5.19 b). The 'real' values of the essential parameters and those in the two dimensional representation can then be compared as shown in table 5.III.
On comparing these quantities it follows (when E_c, E_s, r_s and r_b are equal in both models), that

$$\frac{\lambda_a\ (\text{circ. geom.})}{\lambda_a\ (\text{plane geom.})} \approx \sqrt{-\frac{2(1-\rho)}{\rho \ln \rho}} \quad \text{and} \quad \frac{\lambda_t\ (\text{circ. geom.})}{\lambda_t\ (\text{plane geom.})} \approx \sqrt[4]{\frac{16}{3\pi}} \approx 1.15$$

For $\rho = 0.5$, $\lambda_a(\text{circ})/\lambda_a(\text{plane}) \approx 1.7$ and for $\rho = 0.8$, $\lambda_a(\text{circ})/\lambda_a(\text{plane}) \approx 1.5$.
Apparently the ratios of λ_a and λ_t are independent of d and hence, since only d can be freely adjusted in the model, the ratios are more or less fixed.
Hence, for axial loading especially, the most crucial parameter of the circular structure is badly modeled in the plane representation. As follows from table 5.III also, d can never be chosen in such a way that all other requirements are fulfilled. If $r_s = 5$ mm and $r_b = 10$ mm, then $-\pi/\ln\rho \approx 4.5$ and $4\rho/(1-\rho) = 4$, hence, in order to satisfy requirements for equal C_a, d should be equal to 22.65 and to satisfy requirements for C_t, d should be equal to 10. The requirements for P_s and F_s could be satisfied by assuming non uniform thickness of the stem in the plane model. If d has been chosen to satisfy requirements for C_a or C_t, nothing more can be done to satisfy requirements for F_c, P_c, γ_s and γ_L.

parameter		circular geometry	rectangular geometry

C_t	(1)	$\frac{4\rho E_c(1-\nu_c)}{(1-\rho)(1+\nu_c)(1-2\nu_c)}$	$\frac{2dE_c(1-\nu_c)}{(r_b-r_s)(1+\nu_c)(1-2\nu_c)}$
λ_a^2	(2)	$-\frac{E_c}{E_s}\frac{1}{(1+\nu_c)\ln\rho}\frac{1}{r_s^2}$	$\frac{E_c}{E_s}\frac{1}{2r_s(r_b-r_s)(1+\nu_c)}$
λ_t^4	(2)	$\frac{E_c}{E_s}\frac{4\rho(1-\nu_c)}{(1-\rho)(1+\nu_c)(1-2\nu_c)}\frac{1}{\pi r_s^4}$	$\frac{3}{4}\frac{E_c}{E_s}\frac{1-\nu_c}{(r_b-r_s)(1+\nu_c)(1-2\nu_c)}\frac{1}{r_s^3}$

table 5 III Formulas describing the characteristic parameters in an axisymmetric structure and in a two-dimensional (plane) model (see fig 5 19), (1) rough approximation, see appendix B, (2) to make a 'first-order' general comparison possible $\lambda_a^2 \approx C_a/P_s$ and $\lambda_t^4 \approx C_t/4F_s$ are taken

In conclusion it is evident that unless axial and transverse loading are investigated with two different models and a method of scaling is introduced, the relation between the mechanical behavior of an intramedullary bone prosthesis structure and that of a two-dimensional model is not very well defined This does not imply that two-dimensional FEM models are worthless in this case, when side plates are applied and care is taken to choose the dimensions in such a way as to meet the above mentioned requirements as fully as possible, tendencies could certainly be investigated in a relative sense But these two dimensional models certainly do not have the accuracy that the visual apparent agreements between the models and the real structure suggest Furthermore, a comparison of results of different two dimensional models is difficult

Apart from the fact that in this case, too, a sandwich construction results, the essential characteristics of the structure are not modeled correctly, because those elements that represent the stem also incorporate the stiffness of a piece of cement and a piece of bone and those elements that represent the cement incorporate part of the bone What is modeled correctly in using this method is the overall stiffness of the full cross section McNeice *et al* (1975) show in their results that the stresses in the stem increase by a factor of three if loosening occurs at the stem cement interface This is exactly what would happen in a sandwich construction, as they in fact analyzed, but not in the real structure, where the lateral and medial cortex are connected, as will be shown in the next chapter
A third method of modeling is the one in which the connection between the lateral and medial cortex of the bone is taken into account by applying a side plate or a 'spanning element' layer in the model (fig 5 17.3, e g Hampton *et al*, 1976, Svensson *et al*, 1977) This method is the only one that gives the option of modeling the system as a two beam structure in a plane and hence the only one that is suitable However, it is questionable whether even in using this method the essential parameters mentioned previously can be adequately represented

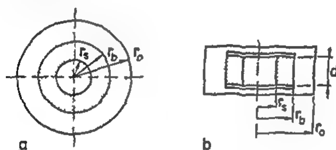

fig 5 19 A plane representation (b) of a structure with axisymmetric cross section (a), applying side plates

As an example, a system with circular cross section is assumed (fig 5 19 a) This structure has to be represented in a plane model, taking a 'spanning element layer into account (fig 5 19 b) The 'real' values of the essential parameters and those in the two dimensional representation can then be compared as shown in table 5 III
On comparing these quantities it follows (when E_c, E_s, r_s and r_b are equal in both models), that

$$\frac{\lambda_a \text{ (circ geom)}}{\lambda_a \text{ (plane geom)}} \approx \sqrt{-\frac{2(1-\rho)}{\rho \ln \rho}} \quad \text{and} \quad \frac{\lambda_t \text{ (circ geom)}}{\lambda_t \text{ (plane geom)}} \approx \sqrt[4]{\frac{16}{3\pi}} \approx 1\ 15$$

For $\rho = 0\ 5$ $\lambda_a(\text{circ})/\lambda_a(\text{plane}) \approx 1\ 7$ and for $\rho = 0\ 8$, $\lambda_a(\text{circ})/\lambda_a(\text{plane}) \approx 1\ 5$
Apparently the ratios of λ_a and λ_t are independent of d and hence, since only d can be freely adjusted in the model, the ratios are more or less fixed
Hence, for axial loading especially, the most crucial parameter of the circular structure is badly modeled in the plane representation As follows from table 5 III also, d can never be chosen in such a way that all other requirements are fulfilled If $r_s = 5$ mm and $r_b = 10$ mm, then $-\pi/\ln\rho \approx 4\ 5$ and $4\rho/(1-\rho) = 4$, hence, in order to satisfy requirements for equal C_a d should be equal to 22 65 and to satisfy requirements for C_t, d should be equal to 10, The requirements for P_s and F_s could be satisfied by assuming non uniform thickness of the stem in the plane model If d has been chosen to satisfy requirements for C_a or C_t, nothing more can be done to satisfy requirements for F_c, P_c, γ_s and γ_b

CHAPTER SIX

INFLUENCES OF NEGLECTED ASPECTS OF THE STRUCTURE

In this chapter some properties of the intramedullary bone prosthesis structure that have been neglected in the previously discussed models and that may influence the mechanical behavior of the system will be discussed These properties are the possible presence of locked in cement stresses, more complicated mechanical conditions at the interfaces, a non-constant cross-sectional geometry of the stem and a few others

6 1 Locked in thermal stresses

Due to the cooling of the acrylic cement, immediately after the polymerization process, the cement layer will shrink around the stem (see also section I)
This will result in locked in stresses that may influence the mechanical behavior of the structure On these (initial) stresses, the stresses resulting from the joint loading will have to be superimposed and, moreover, they may influence the mechanical condition of the stem cement interface that will behave as rigidly connected so long as compression is present When the temperature distribution in the cement right after the polymerization process is known, the shrinkage stresses in an axisymmetric model consisting of bone cement around a (rigid) stem can be calculated (Timoshenko and Goodier, 1970) Using data on tempera ture distributions as discussed in section II, these calculations were carried out for different stem dimensions and cement properties (Huiskes and de Wijn, 1979) Fig 6 1 shows an example of results

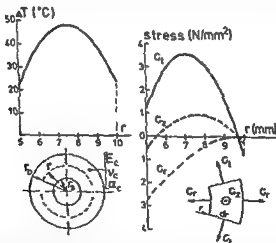

fig 6 1 Locked in thermal stresses in a model of a slice of bone cement The initial tempe rature distribution ΔT (according to fig 7 7, section II) and the radial (σ_r), axial (σ_z) and circumferential (σ_t) stress components are shown Parameter values E_c = 2,000 N/mm², ν_c = 0 33, coefficient of linear expansion α_c = 5x10⁻⁵ °C⁻¹ (according to Ahmed et al, 1977) In the model the properties are taken as inde pendent of the temperature, plane strain state is assumed

It is evident, looking at these results, that for detailed investigations truly three dimensional models should be used FEM beam models as presented in paragraph 5 4 are more dependable, though less refined than two dimensional models

5 6 Conclusions

A simplified axisymmetric model of intrameduallary bone prosthesis structures was analy using various methods A three dimensional FEM model was developed which gives detailed information on the stress distribution in the structure
By comparison of some results with those of strain-gauge experiments on a cadaveric femur with hip endoprostheses, a qualitative agreement was apparent
By making some additional simplifying assumptions, an analytical solution for the most important stress components in the structure could be found by applying beams on elastic foundation theory The most important parameters that characterize the mechanical performance of the structure were thus established
It was found that the structure can be divided into three regions that can be analyzed separately, using quite simple formulas to calculate the most important stress components
The theory, applied here for the analytical solutions, can be extended towards non constant cross-sectional geometry, for example using minimal potential energy principles (Raleigh Ritz) to find a solution Such a solution, however, would not be in closed form, so that numerical methods would have to be applied
A method of this kind was used by Calderale *et al* (1977), for transverse loading
In the present study a FEM beam model was chosen for an extension towards a more rea geometrical description, because this method offers excellent options for model refinement and is quite cheap and practical in use
By applying the concepts developed in this chapter, two dimensional FEM models could be evaluated and it was found that an intramedullary bone prosthesis structure is not very well suited for such representation and that, moreover, many pitfalls are evident in the modeling process

It is felt that the models presented here will give reasonable first order approximations of the intramedullary fixation system mechanical behavior, which implies that the most important parameters of the structure are adequately represented in the models It will be shown in chapters 7 and 8 that the models can conveniently be used to develop quantitative guidelines for implant design and implantation procedures
In the following chapter the influences of properties of the structure that were neglected in the models will be discussed

CHAPTER SIX

INFLUENCES OF NEGLECTED ASPECTS OF THE STRUCTURE

In this chapter some properties of the intramedullary bone prosthesis structure that have been neglected in the previously discussed models and that may influence the mechanical behavior of the system will be discussed These properties are the possible presence of locked in cement stresses, more complicated mechanical conditions at the interfaces, a non-constant cross-sectional geometry of the stem and a few others

6.1 Locked in thermal stresses

Due to the cooling of the acrylic cement, immediately after the polymerization process, the cement layer will shrink around the stem (see also section I)
This will result in locked in stresses that may influence the mechanical behavior of the structure On these (initial) stresses, the stresses resulting from the joint loading will have to be superimposed and, moreover, they may influence the mechanical condition of the stem cement interface that will behave as rigidly connected so long as compression is present When the temperature distribution in the cement right after the polymerization process is known, the shrinkage stresses in an axisymmetric model consisting of bone cement around a (rigid) stem can be calculated (Timoshenko and Goodier, 1970) Using data on tempera ture distributions as discussed in section II, these calculations were carried out for different stem dimensions and cement properties (Huiskes and de Wijn, 1979) Fig 6 1 shows an example of results

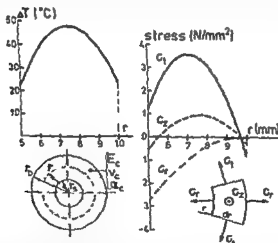

fig 6 1 Locked in thermal stresses in a model of a slice of bone cement The initial tempe rature distribution ΔT (according to fig 7 7, section II) and the radial (σ_r), axial (σ_z) and circumferential (σ_t) stress components are shown Parameter values E_c = 2,000 N/mm², ν_c = 0 33, coefficient of linear expansion α_c = 5x10⁻⁵ °C⁻¹ (according to Ahmed et al, 1977) In the model the properties are taken as inde pendent of the temperature, plane strain state is assumed

The radial (compressional) stress at the stem cement interface reaches a value of approximately 2 5 N/mm² and the hoop stress in the middle of the cement mass 3 5 N/mm² Comparable results were reported by Ahmed *et al* (1977), who have studied the same kind of model These values are quite sensitive to the thickness of the stem For a stem 15 mm in diameter the stress values approximately double if the same initial temperature is assumed However, as was shown in section II, in a thin cement layer the temperature will be much less The hoop stress and the axial stress are also quite sensitive to Poisson's ratio of the cement, while all three stress components are proportional to Young's modulus
The calculated stress values are of the same order of magnitude as the values that have been found to result from the joint loading (appendix A) and thus would certainly interfere with the mechanical behavior of the structure
However, acrylic cement is known to creep, especially under conditions as in the body (see also section I) In a relaxation test of a rod of acrylic cement in water at 37°C, initially under a tensile stress of 4 N/mm², it was found that the stress decreased by 75% in approximately 170 hrs (7 days), as is shown in fig 6 2 (Huiskes and de Wijn, 1979) Extrapolating this data, it can be assumed that after approximately 70 days the stress would have decreased by 90% and after a year would have practically vanished

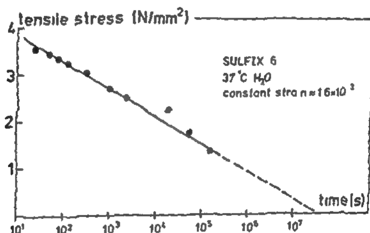

fig 6 2 Stress relaxation in a test bar of acrylic cement in tension

6 2. Mechanical conditions at the interfaces

As mentioned in section I, there is no chemical bond between the stem and the cement nor between the bone and the cement Due to mechanical interlocking of cement and (spongeous) bone the cement bone interface may be able to transfer tensile stresses to some
... present The stem
resistance depends
the cement bone
interface depends on the roughness of the contact surfaces ... compressional stress, hence also on initial locked in stresses
It is rather difficult to take the interface conditions into account in a stress analysis, since not enough accurate data is available for an adequate description Moreover the conditions
... The object of this paragraph is to
... tress distribution in the intra
... that loosening upon tension and

sl p at the stem cement interface significantly affect the stress distribution in the cement, us ng a two dimensional FEM model that can take these phenomena into account In the second and third parts the problem will be approached in a more fundamental fashion, using the concepts developed in paragraph 5 2
The influence of a loose stem will only be evaluated for transverse loading For axial loading the interface conditions would very much depend on friction and on the tapering of the stem When the stem is not held by the friction forces it will simply subside until it again finds support If the stem is held by the friction forces, the interfaces can be assumed to be rigidly connected From a mechanical point of view this problem is further complicated because the friction forces might be exceeded locally

6 2 1 *Numerical evaluation*

The FEM programs as used here offer options to define conditions at contact regions The condition that no tensile stress occurs between two materials can also be taken into account by applying an iterative procedure (Banens, 1977) This method was used for the stem cement interface in a two dimensional model The model and its parameters are described in fig 6 3 A spanning-element layer was used to model the medial lateral cortex connection as discussed in paragraph 5 5 Material properties loading and dimensions in the x z plane were chosen in accordance with the axisymmetric model described in chapter 3

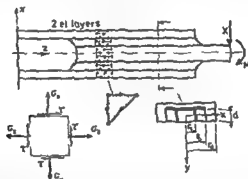

fig 6 3 A two-dimensional FEM model of the simplified intramedullary fixation structure A spanning-element layer (or side plate) is applied, dimensions and stress components are given An element with triangular geometry and 6 nodal points was used, the displacement field in the element is quadratic Note that the x-coordinate is defined as positive opposite to the three-dimensional FEM model (chapter 3)

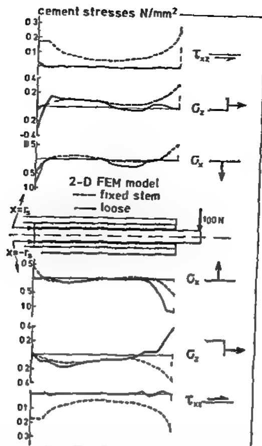
Dimensions in the x y plane were chosen in such a way that the flexural and compressional stiffness of stem and bone (F_s F_b P_s and P_b) were equal to those in the axisymmetric model As discussed in paragraph 5 5 these measures are not sufficient to obtain equivalent results
Calculations were carried out for two cases A rigidly connected stem cement interface and slip and no tension at the interface Fig 6 4 shows a comparison of stresses at the stem cement interfaces as calculated for the two cases apparently the stress distribution in the cement is greatly influenced when a loose stem is assumed
The stresses in the cement at the cement bone interface also differ, as is shown for σ_x in



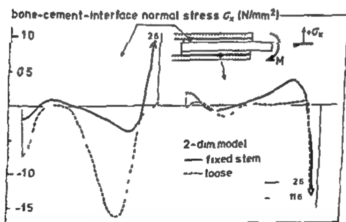


fig 6 4. Stress components in the cement at the stem cement interface on both sides of the stem, calculated for a rigidly fixed interface and as calculated simulating slip and loosening upon-tension The 'noise' in the courses of τ_{xy} for the latter case is due to inaccuracies in the solution procedure

ig 6 5 Transverse stresses at the cement bone interface as calculated for a rigidly connected stem-cement interface and as calculated simulating slip and loosening upon tension at this interface Apparently the latter phenomenon results in the effect that at the cement bone interface also, hardly any tensile stress is present The same effect was found for the shear stresses

fig 6 5 Apparently only very slight tensile stresses occur at this interface in the loose stem case Shear stresses, too, were found to be very low at this interface Hence, little difference would be found for the stress distribution in the cement if the cement bone interface were also assumed loose in addition to the stem cement interface The stem stresses were found to be slightly different, as shown in fig 6 6 It should be noted that the stem stresses do not increase very much in the loose stem case, as would be found for a sandwich construction as discussed in paragraph 5 5, where no side plates are applied in the model The (axial) stresses in the bone do not change significantly for a loose stem

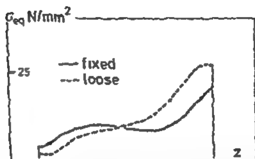

fig 6 6 A comparison of stem (equivalent) stresses as calculated simulating a rigidly connected stem-cement interface and simulating slip and loosening-upon tension at this interface

From the stresses normal to the interface (σ_x) as calculated in the model, the continuously distributed transverse load p(z), as defined in paragraph 5 2, can be derived simply by superposition of the stresses on either side of the stem, multiplied by the stem thickness in y direction (d) It then follows (fig 6 7) that the difference between the results for the two case[illegible]
by [illegible]
effe[illegible]
Both [illegible] separately in the remainder of this paragraph

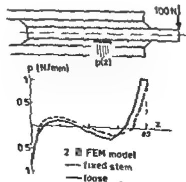

fig 6.7 A comp[illegible]

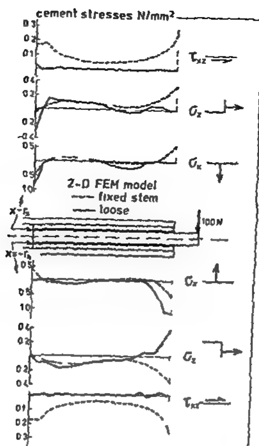

fig 6 4 Stress components in the cement at the stem cement interface on both sides of the stem, calculated for a rigidly fixed interface and as calculated simulating slip and loosening upon tension The 'noise' in the courses of τ_{xy} for the latter case is due to inaccuracies in the solution procedure

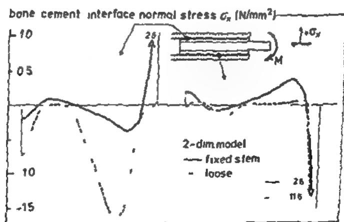

fig 6 5 Transverse stresses at the cement bone interface as calculated for a rigidly connected stem cement interface and as calculated simulating slip and loosening upon tension at this interface Apparently the latter phenomenon results in the effect that at the cement bone interface also, hardly any tensile stress is present The same effect was found for the shear stresses

fig 6 5 Apparently only very slight tensile stresses occur at this interface in the loose stem case Shear stresses, too, were found to be very low at this interface Hence, little difference would be found for the stress distribution in the cement if the cement bone interface were also assumed as loose in addition to the stem cement interface The stem stresses were found to be slightly different, as shown in fig. 6 6 It should be noted that the stem stresses do not increase very much in the loose stem case, as would be found for a sandwich construction as discussed in paragraph 5 5 , where no side plates are applied in the model The (axial) stresses in the bone do not change significantly for a loose stem

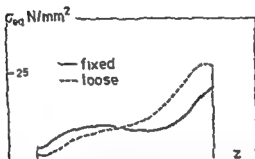

fig 6 6 A comparison of stem (equivalent) stresses as calculated simulating a rigidly connected stem-cement interface and simulating slip and loosening-upon tension at this interface

From the stresses normal to the interface (σ_x) as calculated in the model, the continuously distributed transverse load p(z), as defined in paragraph 5 2, can be derived simply by superposition of the stresses on either side of the stem, multiplied by the stem thickness in y direction (d) It then follows (fig 6 7) that the difference between the results for the [illegible]

[illegible] be evaluated separately in the remainder of this paragraph

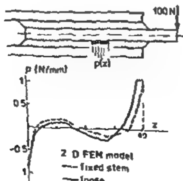

fig 6 7 A comparison of the continuously distributed transverse loads p(z) on the stem as calculated from the FEM results concerning a fixed and a loose stem-cement interface

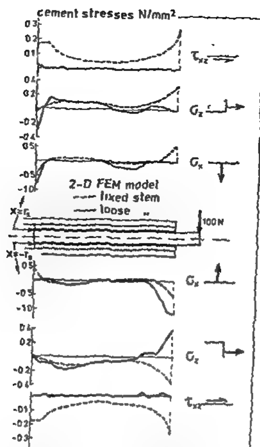

fig. 6.4: Stress components in the cement at the stem-cement interface on both sides of the stem, calculated for a rigidly fixed interface and as calculated simulating slip and loosening-upon-tension. The 'noise' in the courses of τ_{xy} for the latter case is due to inaccuracies in the solution procedure.

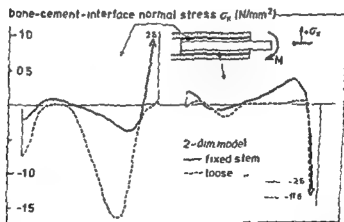

fig. 6.5. Transverse stresses at the cement-bone interface as calculated for a rigidly connected stem-cement interface and as calculated simulating slip and loosening-upon-tension at this interface. Apparently the latter phenomenon results in the effect that at the cement-bone interface also, hardly any tensile stress is present. The same effect was found for the shear stresses.

6 2 3 *The local effect*

The local effect is caused by the circumstance that in the loose case only approximately half of the stem circumference is available to transfer loading As was shown in paragraph 5 2 (fig 5 9), for a fixed stem $p_s(z)$ is found from

$$p_s(z) = -\int_0^{2\pi} (\sigma_r \cos\varphi - \tau_{rt} \sin\varphi) r_s d\varphi$$

Because $\sigma_r = \hat{\sigma}_r \cos\varphi$, $\tau_{rt} = \hat{\tau}_{rt} \sin\varphi$ and $\hat{\tau}_{rt}$ is always opposite in sign as compared to $\hat{\sigma}_r$, it follows that

$$|p_s(z)| = \pi r_s (|\hat{\sigma}_r| + |\hat{\tau}_{rt}|), \text{ for a fixed stem} \qquad (6\ 1)$$

For the case of the loose stem (assuming $\tau_{rt} = 0$) σ_r can be approximated by assuming it to be distributed along half of the stem circumference (fig. 6 9) as a cosine function in φ $\sigma_r = \hat{\sigma}_r \cos\varphi$, $-\frac{\pi}{2} \leq \varphi \leq \frac{\pi}{2}$, so that

$$|p_s(z)| = \frac{\pi}{2} r_s |\hat{\sigma}_r|, \text{ for a loose stem} \qquad (6\ 2)$$

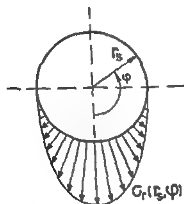

fig 6.9 Radial stress distribution at the stem cement interface, in the case of a loose stem, assumed as a cosine function along half the circumference

It thus follows for $p_s(z)$ with the same local value that $\hat{\sigma}_r$ is at least twice as high in the loose case compared to the fixed case
[illegible]
which calculations is given in fig 6 10 It is evident that for given $p(z)$ the radial stress as well as the hoop stress will be much higher in the loose case In these calculations it was again found that at the cement bone interface the radial stress was distributed only along half the circumference, hence it would make very little difference if this interface were

6 2 2 *The general effect*

It was shown in paragraph 5 2 that, upon transverse loading, the mechanical behavior of the structure is principally determined by the parameters λ_t, F_s, F_b, C_t and L For a loose stem only C_t is affected and, through C_t, also λ_t If we assume circular geometry (axisym metric model) the value of C_t can be approximated by (appendix B)

$C_t \approx 6\ 2 E_c(0\ 24 + \frac{\rho}{1-\rho})$ for a rigidly connected interface and

$C_t \approx 2\ 1 E_c(0\ 24 + \frac{\rho}{1-\rho})$ for a loose interface

It then follows that

C_t(loose stem)/C_t(fixed stem) $\approx$ 0 34
λ_t(loose stem)/λ_t(fixed stem) $\approx$ 0 76

The stem will thus 'feel' a more flexible layer in the loose case and the force introduction regions at the proximal and the distal sides will be more extended
Also, the maximal values of p(z) at the proximal and distal sides will be lower in the loose case, since both depend on C_t/λ_t^2 and C_t/λ_t^3 (table 5 II)
In fig 6 8 it is shown, for example how this change in C_t affects $M_s(z)$, $M_b(z)$ and p(z), as calculated with the beams on elastic foundation model described in paragraph 5 2

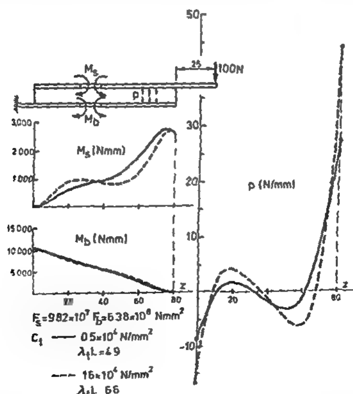

fig 6 8 Bending moments in stem and bone ($M_s(z)$ and $M_b(z)$) and distributed transverse load p(z) calculated using the beams-on elastic-foundation model, for two different values of C_t, simulating a fixed stem (C_t = 1 6x10^4 N/mm^2) and a loose stem (C_t = 0 5x10^4 N/mm^2)

It was shown that the loosening upon tension aspect of the stem cement interface has a moderate general effect on the mechanical behavior of the structure and an outspoken local effect, mainly on the cement and interface stresses The general effect can be taken into account by adjusting the value of C_t and the local effect by interpreting the continuously distributed transverse load p(z) as working on half the stem circumference only If it is the object to evaluate the stress distribution in the cement layer and at the interfaces in detailed three dimensional FEM models, the slip and loosening upon tension aspects should be taken into account Once this is done for the stem cement interface, the conditions at the cement bone interface will not have much influence anymore

6 3 Nonconstant cross sectional properties of the stem

For the analyses discussed in chapter 5, it was assumed that the cross-sectional properties of the stem (F_s and P_s) were constant The stem may be tapered to some extent and since Young's modulus is constant, F_s and P_s will be functions of z, as well as C_t and C_a It can be anticipated that for a slight taper the formulas derived in chapter 5 will still apply by

functions of z

A first order evaluation of the taper influence can be established by regarding the influences on $\lambda_t(z)$ and $\lambda_a(z)$ Three different stem shapes are assumed (fig 6 11) in an example (axi symmetric structure) For λ_t and λ_a it can be found (taking C_t and C_a according to appendix B) that

$$\lambda_t = A_1 \sqrt[4]{\left\{ \frac{\rho}{1-\rho} \left(\frac{F_b}{F_s} + 1 \right) \right\}} \quad \text{and} \quad \lambda_a = A_2 \sqrt{\left\{ \frac{-1}{\ln \rho} \left(\frac{P_b}{P_s} + 1 \right) \right\}}$$

where $\rho = r_s/r_b$ and A_1 and A_2 are constants depending on E_c, ν_c, E_b, the bone dimensions and the interface conditions

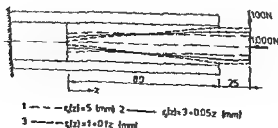

fig 6 11 The three different stem shapes investigated with the FEM beam model

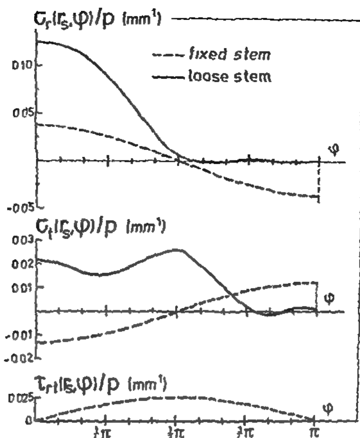

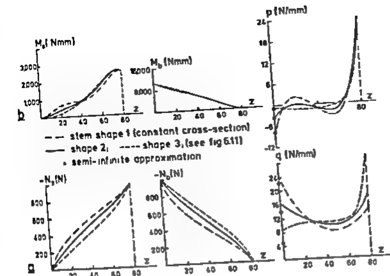

fig 6 10 Radial, circumferential and shear stress distribution on half the circumference of the stem cement interface, as calculated using FEM in a slice of the structure, for a loose stem and a fixed stem (Huiskes and Schouten, 1979) The stress components are given as relative to the local value of the transverse load p(z) The 'noise' in the curves of the stresses in the case of a loose stem is caused by the solution procedure (Fourier expansion)

assumed to be loose in addition, which could be concluded also from the results discussed in paragraph 6 2 1

6 2 4 *Conclusions*

In reality the interface conditions will be more complicated Friction will most certainly occur and locked in stresses may also be present, at least directly postoperatively Even in the idealized axisymmetric model discussed here, the interface behavior is nonlinear, because in principle the contact area changes with the load For a loose stem, no initial locked in stresses, assuming a contact area over half the stem circumference results in a reasonable approximation of the stress distribution (Schoofs, 1979) In the case that locked in stresses are present, the non linear effect will be more pronounced In this case, that will occur during the initial postoperative period, a C_t value in accordance with a fixed stem is an upper boundary and one in accordance with a loose stem a lower boundary for the apparent cement layer stiffness

mation, using the local stem radius in the formulas.

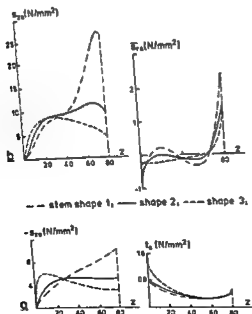

fig 6.14: Stem and cement stresses on axial loading (a) and on transverse loading (b), as calculated for the three stem shapes

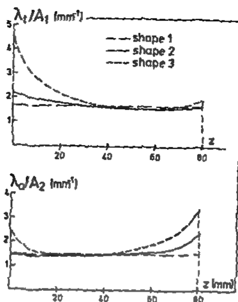

fig 6 12 The coefficients λ_t and λ_a as functions of z for the three stem shapes (for the constants A_1 and A_2 see text)

For the tapers shown in fig 6 11 the courses of λ_t/A_1 and λ_a/A_2 as functions of z were evaluated, as shown in fig 6 12 It can be anticipated, looking at these graphs, that in transverse loading there will be little difference in the mechanical behavior of the structure on the proximal side, but a significant difference on the distal side, especially where the pronounced taper is concerned In axial loading there should be little difference for the moderate taper compared to the constant cross sectional shape on the distal side and some difference on the proximal side, there should be a marked difference for the pronounced taper compared to the constant shape
Nonconstant cross sectional properties of the structure can be taken into account in the FEM beam model, as described in paragraph 5 4 This model was used to calculate p(z), q(z), $M_s(z)$, $M_b(z)$, $N_s(z)$ and $N_b(z)$ for the examples shown in fig 6 11 Results are shown in fig 6 13 It follows from these graphs, on consideration of the courses of p(z) and q(z), that the predictions expressed previously are fulfilled Nevertheless the difference in q(z) at the distal side for the moderate taper shape compared to the constant shape is somewhat more outspoken than anticipated Since in the case of the straight stem $\lambda_t L \approx 5\ 0$ and $\lambda_a L \approx 2\ 9$, this non predicted difference is probably caused by a significant influence from the proximal side on the distal side in axial loading (as discussed in paragraph 5 3, π/λ_a determines the length of the load introduction regions for axial loading)
It is also found that the maximal values of p(z) and q(z) on the distal side can be predicted by approximation with the formulas presented in table 5 II using the local value of r_s (respectively r_s = 5,3 and 2 mm) For transverse loading especially this approximation is excellent, as shown in fig 6 13 At the proximal side such an approximation does not succeed, probably owing to a stronger dependency of the stress variables on F_s and P_s (see table 5 II), and a higher sensitivity of C_t and C_a for the (varying) ratio ρ in this region, because of the small thickness of the cement layer

Since the stem thickness varies, $M_s(z)$, $N_s(z)$, p(z) and q(z) are no longer proportional to the stem, cement and cement stem interface stresses Representative of these stresses are the average transverse stress at the interface $\bar{s}_{rs} = p/2r_s$ and the maximal axial stem stress $s_{zs} = M_s/W_s$, in transverse loading, and the interface shear stress $t_s = q/\gamma_s$ and the maximal

in chapter 4 so that the varieties in F_b and P_b are probably not very pronounced Since the stem and the bone play analogue but inverse roles with respect to the proximal and distal sides the same kind of reasoning as for the nonconstant stem shape applies Also in this case the influences of arbitrary variations in z can be evaluated by using the FEM beam model

It is not known whether, due to the trabecular bone in the epiphyseal regions of the bones, deviations from beam theory might occur It is to be expected, because, as was shown in paragraph 5 1 , in the schematized 'bone' with homogeneous properties assumed, deviations from beam theory already occurred (fig 5 5)
In for instance the proximal tibia, this effect will be more pronounced than in the proximal femur, since in the latter case cortical bone is present in the calcar region (on the medial side) where the greater part of the (transverse) load is introduced, due to the loosening upon tension aspect of the stem cement interface
Due also to the epiphyseal spongeous bone, which serves as an elastic layer, the peak values in p(z) and q(z) could be lower and the load introduction somewhat smoother (smaller λ_t and λ_a) as indeed is apparent in the results from the three dimensional models of Scholten *et al* (1978), where non homogeneous bone properties are taken into account These effects can also be investigated by means of the FEM beam model
Apart from the inhomogeneous properties of the bone anisotropy was also neglected in the models, as well as the slight curvatures of the stem and the bone It is expected that these phenomena will not affect the qualitative aspects of the model results

It has been shown in paragraph 5 2 that the formulas derived for the characterization of the mechanical behavior of the structure are valid for arbitrary cross-sections of the stem and the bone while for circular geometry examples were evaluated This means that the local influences of different stem cross-section geometries can be studied perfectly by modeling local sections as was done by Crowninshield and Branch (1978) For such studies the local loading can be derived from more general beams-on-elastic foundation or FEM beam analyses as discussed here

Effects that likewise were not taken into account here are those that may follow from the

— collar calcar contact (*if a collar is present*),

axial stem stress $s_{zs} = N_s/A_s$ in axial loading, as defined in paragraph 5 2 These stress quantities are shown in fig 6 14 for the three different stem shapes The courses of $s_{zs}(z)$ for the tapered stems are very much like the stem stresses that were measured by Huggler *et al* (1978) in strain gauge experiments on hip prostheses in cadaveric femurs, and the courses of $s_{zs}(z)$, $\bar{s}_{rs}(z)$ and $t_s(z)$ are comparable to results of three dimensional FEM models (e g Sch
and at the cemer
$N_b(z)$, $p(z)$ and c
it is evident that the use of a tapered stem benefits the system performance In transverse loading the pronounced taper shows the best results, in axial loading the moderate taper In chapter 8 the stem shape will be further discussed

In the literature, composite beam theory is often used to evaluate the stresses in the stem (e g Bartel and Desormeaux, 1976a, Walker, 1977, Swanson and Freeman, 1977) As we have seen in paragraph 5 3 , this approximation is valid for the middle region of structures with constant cross section, if $\lambda_t L$ and $\lambda_a L$ are sufficiently large For tapered stems the *approximation may be rather poor, as is illustrated in fig 6 15 for the moderately tapered stem*

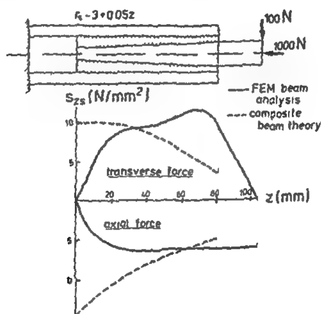

fig 6 15 A comparison of stem stresses on axial and transverse loading, as calculated for stem shape no 2, using the FEM beam model and composite beam theory, the latter method is in this case not very accurate

6 4 Other aspects

the

physis (with a lower Young's modulus)
the geometrical and material stiffness, however, work in opposite directions, as was discussed

Likewise the coefficient λ_w in torsion, that determines the lengths of the proximal and distal regions has the same form as λ_a in axial loading. For $\rho = 0.5$ it follows (assuming the reference values as discussed in chapter 3 for the other parameters) that $\lambda_a \approx 0.04$ mm^{-1} and $\lambda_w \approx 0.06$ mm^{-1}, for $\rho = 0.8$, $\lambda_a \approx 0.05$ mm^{-1} and $\lambda_w \approx 0.08$ mm^{-1}.
In conclusion, the proximal and distal regions will be shorter in torsional loading compared to axial loading and, qualitatively speaking, the same tendencies that are found for axial loading apply to torsional loading.
It should be remarked here that one should be rather careful with these formulas for torsional loading, since they have not been verified in a FEM analysis.
Furthermore, especially for non circular geometries the mechanical behavior of the structure may be quite complicated in torsion.

- thermal locked in stresses (initial stresses, no loosening upon tension at the cement stem interface),

later postoperative

- no collar calcar contact,
- no thermal locked in stresses (loosening upon tension, hence a lower C_t value for the cement mantle, decreased λ_t, less friction),
- osteoporosis (decreasing F_b and P_b, hence increasing λ_t and λ_a),

late postoperative

- calcar resorption (increased free stem length, reduced fixation length),
- further osteoporosis (decreasing F_b and P_b, increasing λ_t and λ_a, especially at the proximal side),
- cement ageing (reduced E_c, reducing C_a and C_t, λ_a and λ_t),
- fibrous tissue layer at the cement bone interface

An interesting investigation would be to follow such processes and roughly quantify the effects of the changes on the stress distribution in the structure For such a study the analytical concepts and the FEM beam model developed here can be used, combined with radiographical or (in animal studies) histological data

Another aspect that has been neglected here, and indeed has received little attention in orthopedic biomechanics literature, is the incidence of torsion on the stem Torsion will occur in the artificial hip joint, as was shown for instance by Rydell (1966) (see section 1), and will even be the most important loading case in the elbow joint For a first order evaluation of the effect of torsional loading the axisymmetric model can again be used Also in this case the Winkler hypothesis can be applied to the cement layer Its stiffness is then represented by a continuous set of linear torsional springs The mechanical behavior of the structure in torsion is described by torsional moments in the stem and the bone and by a continuously distributed shearing moment at the interfaces (Nmm/mm), as functions of z Here, too, the stiffness of the cement mantle can be approximated by a stiffness factor comparable to C_a in axial loading If the differential equations are formulated in the tangential displacements of the outer stem and the inner bone circumferences, they are found to be completely analogous with those of the axial loading case, boundary conditions included Hence the solutions are identical, except for the expressions of the stiffness factors A comparison of stem, bone and cement stiffness factors is shown in table 6 1

	axial loading		torsional loading		
cement mantle (C_a in axial loading)	$-\frac{\pi E_c}{(1+\nu_c)\ln\rho}$	(N/mm²)	$\frac{\pi\rho E_c r_b}{(1-\rho)(1+\nu_c)}$	(1)	(N/mm)
stem (P_s in axial loading)	$\pi r_s^2 E_s$	(N)	$\frac{\pi E_s r_s^3}{4(1+\nu_s)}$		(Nmm)
bone (P_b in axial loading)	$\pi E_b(r_o^2 - r_b^2)$	(N)	$\frac{\pi E_b(r_o^4 - r_b^4)}{4r_b(1+\nu_b)}$		(Nmm)

table 6 1 Structural stiffness factors of the stem, the bone and the cement mantle (axisymmetric model) in torsional loading compared to those for axial loading (1) reasonable approximation when ρ is sufficiently close to 1

Likewise the coefficient λ_w in torsion, that determines the lengths of the proximal and distal regions has the same form as λ_a in axial loading. For $p = 0.5$ it follows (assuming the reference values as discussed in chapter 3 for the other parameters) that $\lambda_a \approx 0.04\ mm^{-1}$ and $\lambda_w \approx 0.06\ mm^{-1}$, for $p = 0{,}8$, $\lambda_a \approx 0.05\ mm^{-1}$ and $\lambda_w \approx 0.08\ mm^{-1}$.

In conclusion, the proximal and distal regions will be shorter in torsional loading compared to axial loading and, qualitatively speaking, the same tendencies that are found for axial loading apply to torsional loading.

It should be remarked here that one should be rather careful with these formulas for torsional loading since they have not been verified in a FEM analysis.

Furthermore, especially for non circular geometries the mechanical behavior of the structure may be quite complicated in torsion.

CHAPTER SEVEN

THE INFLUENCES OF THE ESSENTIAL PARAMETERS

7 1 Premises

The influences of the essential parameters on the mechanical behavior of the bone prosthesis structure can be evaluated with the formulas derived in paragraph 5 3 (see table 5 II) and by applying parametric analysis, using the other models discussed in chapter 5
For reasons of convenience, the factors in the formulas of table 5 II are denoted as follows

proximal region $\alpha_m = \frac{1}{2}\frac{C_t}{\lambda_t^2 F_s}$, $\alpha_t = \frac{1}{2}\frac{C_t}{\lambda_t^3 F_s}$, $\alpha_n = \frac{\lambda_a P_b}{P_s + P_b}$,

distal region $\beta_m = \frac{1}{2}\frac{C_t}{\lambda_t^2 F_b}$, $\beta_t = \frac{1}{2}\frac{C_t}{\lambda_t^3 F_b}$, $\beta_n = \frac{\lambda_a P_s}{P_s + P_b}$,

middle region $\epsilon_m = \frac{F_s}{F_s + F_b}$, $\epsilon_n = \frac{P_s}{P_s + P_b}$,

where λ_t and λ_a can be evaluated from

$$\lambda_t = \sqrt[4]{\left\{\frac{C_t}{4}\left(\frac{1}{F_s} + \frac{1}{F_b}\right)\right\}} \quad \text{and} \quad \lambda_a = \sqrt{\left\{C_a\left(\frac{1}{P_s} + \frac{1}{P_b}\right)\right\}}$$

Using these two expressions the factors α_m through ϵ_n can be rewritten as functions of C_t, C_a F_s F_b P_s and P_b only
These forms are valid for arbitrary cross sectional geometry, C_a and C_t can be approximated using the formulas presented in appendix II
Using the factors defined above the stress variables for the proximal distal and middle regions as defined in paragraph 5 3 can be expressed as shown in table 7 I, these stresses are once more illustrated in fig 7 1 By considering these formulas and the expressions for the factors α_m through ϵ_n (taking the expressions for λ_t and λ_a into account) the influences of the structural parameters on the most important stresses can be directly evaluated
In table 7 II these influences are given qualitatively

In the following paragraphs the parameter influences are discussed separately, mainly using the formulas but also as follows from parametric analyses with the other models

7 2 The stem length

The length of the stem, together with the values of λ_t and λ_a determine whether the proximal and distal stresses influence each other and whether there is a middle region that behaves approximately in accordance with composite beam theory

stress component	proximal region (z = L)	distal region (z = 0)
$s_{zs} = \frac{M_s}{W_s} + \frac{N_s}{A_s}$	$\frac{M_L}{W_s} + \frac{N_L}{A_s}$	0
$\bar{s}_{rs} = \frac{p}{2r_s}$	$\frac{\alpha_m}{2r_s} M_L + \frac{\alpha_t}{2r_s} T_L$	$-\frac{\beta_m}{2r_s}(M_L + T_L L) + \frac{\beta_t}{2r_s} T_L$
$\bar{s}_{rb} = \frac{p}{2r_b}$	$\frac{\alpha_m}{2r_b} M_L + \frac{\alpha_t}{2r_b}$	$-\frac{\beta_m}{2r_b}(M_L + T_L L) + \frac{\beta_t}{2r_b} T_L$
$t_s = \frac{q}{\gamma_s}$	$-\frac{\alpha_n}{2\pi r_s} N_L$	$-\frac{\beta_n}{2\pi r_s} N_L$
$t_b = \frac{q}{\gamma_b}$	$-\frac{\alpha_n}{2\pi r_b} N_L$	$-\frac{\beta_n}{2\pi r_b} N_L$

middle region $s_{zs} = \frac{M_s}{W_s} + \frac{N_s}{A_s} = \frac{\epsilon_m}{W_s}(M_L + T_L(L-z)) + \frac{\epsilon_n}{A_s} N_L$

table 7 I Approximative formulas describing the most important stress variables in the stem, the bone, in the cement layer and at the interfaces in the proximal, middle and distal regions respectively (see also table 5 II and fig 7 1)

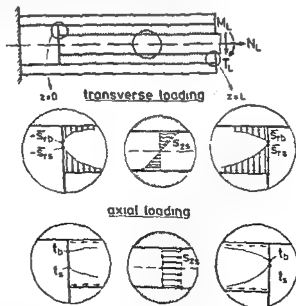

fig 7 1 An illustration of the stress components in the stem, the bone, the cement and at the interfaces, on transverse and axial loading, as described by the approximative formulas

	C_t	F_s	F_b	C_a	P_s	P_b
proximal:						
α_m	+	−	+	o	o	o
α_t	+	−	+	o	o	o
α_n	o	o	o	+	−	+
distal:						
β_m	+	+	−	o	o	o
β_t	+	+	−	o	o	o

middle:						
ϵ_m	o	+	−	o	o	o
ϵ_n	o	o	o	o	+	−

table 7.II: Qualitative influences of the single characteristic structural parameters on the factors α, β and ε; for (+) the factor increases with increasing parameter value, for (−) it decreases, for (o) there is no influence.

It should be kept in mind that, generally speaking, the stresses at the proximal and distal sides are lower when they do not influence each other and that the middle region serves no purpose in the prosthesis bone load transmission

For values of approximately $\lambda_t L \gtrapprox \pi$ and $\lambda_a L \gtrapprox \pi$ there is little influence from the distal on the proximal side and vice versa This means also, that when the stem length is extended beyond $L \approx \pi/\lambda_t$ and $L \approx \pi/\lambda_a$, this has very little influence on the stresses in the structure resulting from the respective loading cases However, there is one exception as shown in tables 5 II and 7 I, L appears in the formulas for the distal stresses ($p(0)$, $s_{rs}(0)$ and $s_{rb}(0)$) and the stem stresses in the middle region ($s_{zs}(z)$) as a coefficient of T_L, the transverse force. Hence, for this loading case it is of importance to keep the length restricted, a more or-less 'optimal' value would then be $L \approx \pi/\lambda_t$

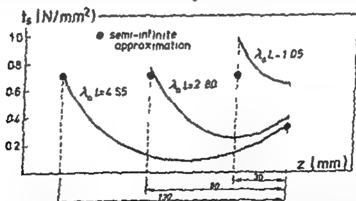

fig 7.2: Shear stress at the stem-cement interface on axial loading as calculated using the beams-on-elastic-foundation theory, for three different lengths of the stem Also indicated are the values for q(0) and q(L) as calculated using the semi-infinite approximation, which is appropriate when $\lambda_a L$ is sufficiently high.

Fig 7 2 gives an example of $\tau_s(z)$ upon axial loading as calculated for three different stem lengths, using the beams-on-elastic foundation theory described in paragraph 5 2 2 , the values that result from the semi infinite theory, using the formulas of table 7 1, are also shown It is evident that for L > 80 mm, extending the length has little effect on the maximal stress values As follows again from fig 7 2, the semi infinite approximation is better for the longer stems

Fig 7 3 shows an example of the courses of $M_s(z)$, $M_b(z)$ and $p(z)$ upon transverse loading for three different stem lengths, as calculated with the theory described in paragraph 5 2 1 It should be noted that a dimensionless coordinate (z/L) is used on the horizontal axis Extending the length from 80 to 130 mm has no effect on the proximal stresses and a negative effect on the distal cement stresses and the stem stresses, due to the previously described influence of τ_L In this case, too, the semi infinite approximations of p(0) and p(L) are indicated in the figure

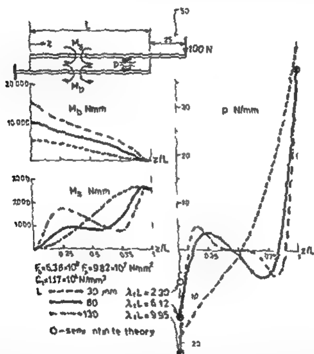

fig 7 3 Bending moments in the stem and the bone ($M_s(z)$ and $M_b(z)$) and the continuously distributed transverse load p(z) as calculated with the beams-on-elastic foundation theory for three different stem lengths Note that, in this case, z/L is put on the horizontal axis The values for p(0) and p(L) as calculated with the approximative formulas are also indicated For the very short stem these formulas no longer apply very accurately

The ... [illegible] ... ...dation models, but several stress components

in the cement layer are neglected These components show the same tendencies as the ones discussed above, as for example is shown in fig 7 4 as regards the hoop stress (σ_t), the axial stress (σ_z) and the shear stress (τ_{rz}) in transverse loading

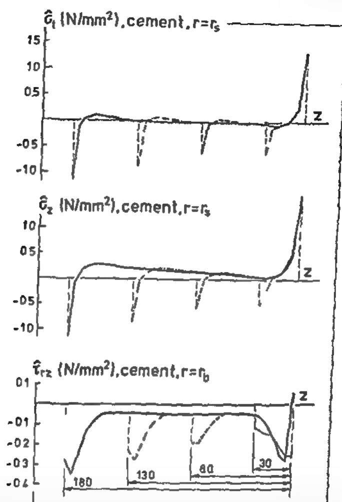

fig 7 4 Hoop stresses and axial stresses in the cement layer at the stem-cement interface and shear stresses at the cement bone interface as calculated with the three-dimensional FEM model, on transverse loading, for four stem lengths

7.3. The structural stiffness of the cement mantle

The factors α_m and β_m are proportional to $\sqrt{C_t}$, α_t and β_t to $\sqrt[4]{C_t}$ and α_n and β_n to $\sqrt{C_a}$ Hence, all important cement and interface stresses will decrease with decreasing C_t and C_a Also, λ_t and λ_a are influenced by C_t and C_a, respectively In general it can be said that the load introduction at the proximal and distal sides will be smoother for lower values of C_t and C_a

Fig. 7.5 shows an example of values for $M_s(z)$, $M_b(z)$ and $p(z)$ on transverse loading as calculated for three values of C_t, using the beams on elastic foundation theory The decrease in the proximal and distal maximal values of $p(z)$ on decreasing C_t is apparent The stresses in the stem are only slightly influenced Owing to the decreasing value of λ_t, with decreasing C_t the middle region is shortened The same effects are apparent in axial loading For low C_a, the shear stresses will tend to be smoothened towards a constant value over the length of the

structure There is only a minor influence on the stem and the bone stresses in this case, too

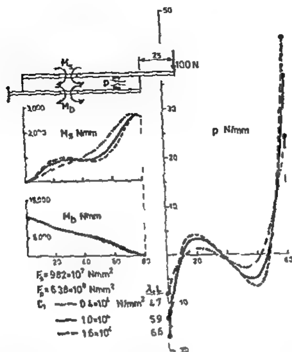

fig 7 5 $M_s(z)$, $M_b(z)$ and $p(z)$ as calculated with the beams-on-elastic foundation theory for three different values of C_b, keeping the other parameters (F_s, F_b and L) constant

C_t and C_a depend on the thickness the Young s modulus and the Poisson s ratio of the cement layer The layer thickness depends on the dimensions of the stem and the bone, which will be discussed later C_t and C_a are directly proportional to E_c C_t is by approximation proportional to $(1-\nu_c)/(1+\nu_c)(1-2\nu_c)$ (appendix B), for $0.2 \leq \nu_c \leq 0.4$, this factor varies from approximately 1 1 to 2 1 C_a is by approximation proportional to $1/(1+\nu_c)$, which varies from only 0 8 to 0 7 in the above mentioned range Hence overall, a low value of ν_c is advantageous

These effects were again confirmed for other stress components as well with the three dimensional FEM model (Huiskes 1977 Huiskes and Slooff, 1978) Only in one respect did this model give additional information the value of ν_c has a marked influence on the axial and hoop stresses in the cement mantle, as shown in fig 7 6

7 4 The structural stiffness of the stem

The structural stiffness of the stem expressed in E and D ...

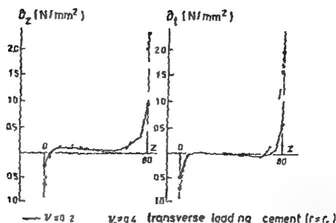

fig 7 6 Axial and hoop stresses in the cement at the stem-cement interface, on transverse loading as calculated with the three dimensional FEM model for two different values of ν_c

The values of α_m α_t and α_n will also decrease causing p(L) and q(L) (proximal side) to decrease, β_m β_t β_n ϵ_m and ϵ_n will increase as a result of which p(0) and q(0) (distal side) $M_s(z)$ and $N_s(z)$ (middle region) increase This is illustrated in fig 7 7 for transverse loading where $M_s(z)$ $M_b(z)$ and p(z) are shown as calculated for three values of F_s using the beams on elastic foundation model Apparently p(L) is more sensitive to F_s than p(0) due to the fact that β_m for example is approximately proportional to $\sqrt{F_s}$ and α_m to $1/F_s$

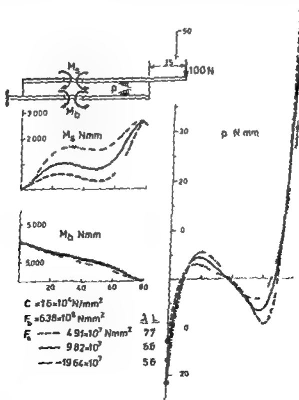

fig 7 7 $M_s(z)$, $M_b(z)$ and p(z) on transverse loading, as calculated with the beams-on-elastic foundation theory for three different values of F_s, keeping the other parameters (F_b C_t and L) constant

Changing F_s and P_s without affecting other parameters is only possible by changing E_s. In this case the structure will be influenced purely as described above. This was again confirmed for other stress components in the cement on application of the three-dimensional FEM model (Huiskes 1977, Huiskes and Slooff, 1978).

When the thickness of the stem is changed, apart from the influences on F_s and P_s, two other effects play a role: the thickness of the cement layer changes, hence C_a and C_t are influenced, and the load transferring area of the stem cement interface (represented by r_s) changes, which has a local effect on the stresses. At the proximal side the first effect (F_s and P_s) and the last effect (r_s) combine to decrease or increase the stresses, but the second effect (C_t and C_a) works in the opposite direction. At the distal side the first effect (F_s and P_s) and the second effect (C_t and C_a) combine to decrease or increase the stresses, but the third effect (r_s) works in the opposite direction. In the middle region C_t and C_a have little influence on the stem stresses, the other two effects work in opposite directions. Hence optimal values for the stem thickness in the different regions should be expected to exist. For circular geometry these effects are evaluated in the figs 7.8 through 7.10 as the influences of the stem radius on the factors α and β. It is evident that on the distal side the stem should, for all stress components, be as thin and flexible as possible. On the proximal side the stem material should be as stiff as possible, for the stem thickness, however, there is an optimum value that in this case (the chosen bone properties) is $r_s \approx 8$ 9 mm (layer thickness of 1 2 mm) on transverse loading, and $r_s \approx 6$ [illegible] mm (layer thickness of 2 4 mm) on axial loading.

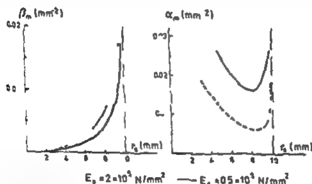

fig 7.8 *The factors α_m and β_m as functions of r_s (circular geometry), for two different values of E_s.*

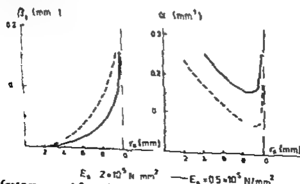

fig 7.9 *The factors α_t and β_t as functions of r_s (circular geometry) for two different values of E_s.*

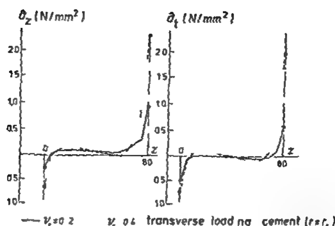

fig 7 6 Axial and hoop stresses in the cement at the stem-cement interface, on transverse loading, as calculated with the three dimensional FEM model for two different values of ν_c

The values of α_m α_t and α_n will also decrease, causing p(L) and q(L) (proximal side) to decrease, β_m β_t, β_n ϵ_m and ϵ_n will increase, as a result of which p(0) and q(0) (distal side) $M_s(z)$ and $N_s(z)$ (middle region) increase This is illustrated in fig 7 7 for transverse loading where $M_s(z)$ $M_b(z)$ and p(z) are shown as calculated for three values of F_s using the beams on elastic foundation model Apparently p(L) is more sensitive to F_s than p(0) due to the fact that β_m for example is approximately proportional to $\sqrt{F_s}$ and α_m to $1/F_s$

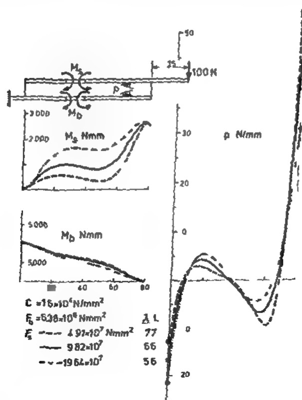

fig 7 7 $M_s(z)$, $M_b(z)$ and p(z) on transverse loading, as calculated with the beams-on-elastic foundation theory for three different values of F_s keeping the other parameters (F_b C_t and L) constant

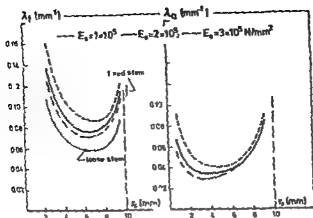

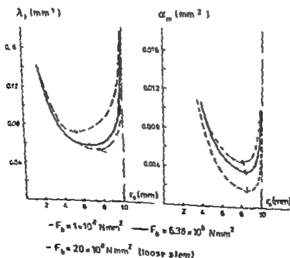

fig 7 11 The coefficients λ_t and λ_α as functions of r_s (circular geometry) for different values of E_s

7 5 The structural stiffness of the bone

As regards the mechanical behavior of the structure, the roles of F_b and P_b are equivalent [illegible]

α_m α_t and α_n will increase, causing p(L) and q(L) (proximal region) to increase, β_m, β_t, β_n ϵ_m and ϵ_n will decrease as a result of which p(0) and q(0) (distal region) and $M_s(z)$ and $N_s(z)$ (middle region) decrease

he coefficient λ_t and the factor α_m as functions of r_s (circular geometry) for ree different values of F_b

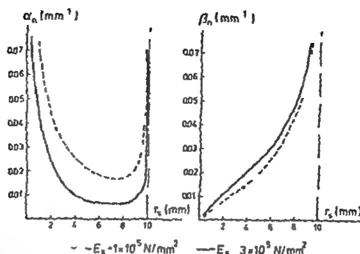

fig 7 10 The factors α_n and β_n as functions of r_s (circular geometry), for two different values of E_s.

The values of r_s for which the minima in α_m, α_t and α_n occur are independent of E_c, ν_c and the interface conditions As follows from figs 7 8 through 7 10, they are not very sensitive for the stem Young's modulus, too Since the factors $-1/\ln\rho$ and $\rho/(1-\rho)$ (on which C_a and C_t depend) are rather strong for ρ close to 1, the locations of the minima will thus be determined by $r_b - r_s$ (the layer thickness), rather than by the stem thickness itself Hence, the optimal values for the layer thickness mentioned above can probably be regarded as generally applicable It should be remarked, however, that in this case the presence of a soft bone layer (spongeous bone) was not taken into account

In the middle region the stem stresses decrease for a thicker stem on axial loading On transverse loading the stem stresses will be lower for a thin stem as well as for a very thick stem, for circular geometry, a maximum occurs for $r_s = \sqrt[4]{(16F_b/3\pi E_s)}$ For both the transverse and axial loading cases the stem stresses decrease on decreasing Young's modulus of the stem material On transverse loading the stem stresses are almost proportional to the modulus, on axial loading the influence is somewhat less pronounced

The thickness of the stem also affects the coefficients λ_a and λ_t Here, too, the effects of the changes in the stem stiffness and the cement mantle stiffness work in opposite directions, hence minimal values for λ_a and λ_t exist
For circular geometry the influences of the stem thickness (r_s) on the values of λ_a and λ_t are shown in fig 7 11

In a cross section of the structure the total bending moment and the total axial force follow from

$M(z) \approx M_s(z) + M_b(z)$ and $N(z) \approx N_s(z) + N_b(z)$

In using these formulas the influence of the structural stiffness of the stem on the bone stresses can directly be evaluated if the effect on the stem stresses is known

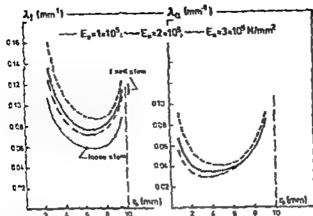

fig 7 11 The coefficients λ_t and λ_a as functions of r_s (circular geometry) for different values of E_s.

7 5 The structural stiffness of the bone

As regards the mechanical behavior of the structure, the roles of F_b and P_b are equivalent to those of F_s and P_s, but inversed at the proximal and distal sides When E_b and r_o change, only F_b and P_b are affected Higher values of F_b and P_b will reduce λ_t and λ_a, respectively, so that the proximal and distal load-introduction regions will be extended The values of α_m, α_t and α_n will increase, causing p(L) and q(L) (proximal region) to increase, β_m, β_t, β_n, e_m and e_n will decrease as a result of which p(0) and q(0) (distal region) and $M_s(z)$ and $N_s(z)$ (middle region) decrease

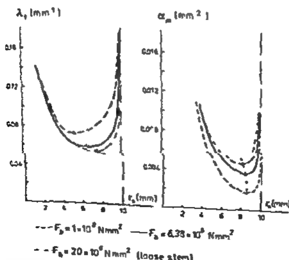

fig 7 12 The coefficient λ_t and the factor α_m as functions of r_s (circular geometry) for three different values of F_b.

For circular geometry the influences of F_b on $\lambda_t(r_s)$ and $\alpha_m(r_s)$ are shown in fig 7 12, assuming a constant inner bone radius (r_b) and constant stem and cement materials properties Apparently the value of r_s for which the minimum in α_m occurs is not very sensitive for F_b also

If r_b changes then the cement layer thickness also changes In this case it can be expected, as discussed in paragraph 7 4, that a layer thickness of around 2 mm will still be an optimum where the stresses at the proximal side are concerned

These tendencies were again confirmed by the results of the three-dimensional FEM model (Huiskes, 1977) Fig 7 13 shows an example of stem, cement and bone equivalent stresses on transverse and axial loading for two different Young's moduli of the bone

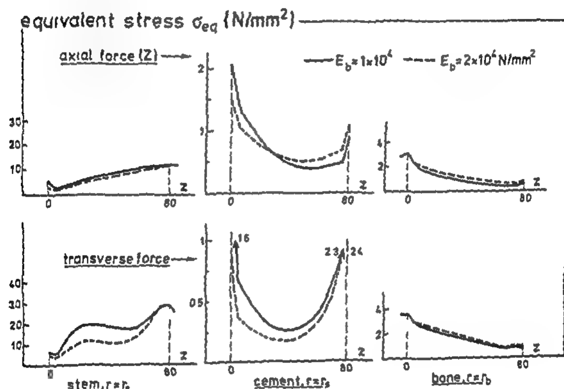

fig 7 13 Equivalent stresses in stem, bone and cement (at the stem-cement interface) on axial loading and transverse loading as calculated with the three dimensional FEM model, for two different values of E_b.

CHAPTER EIGHT

GUIDELINES FOR STEM DESIGNS AND IMPLANTATION PROCEDURES

In the previous chapter the influences of the characteristic parameters of the structure on its mechanical behavior were studied It was shown that the analytical models, described in chapter 5, could conveniently be used for these parametric analyses and that, by using the approximative formulas, practically all influences could be evaluated The results of the three-dimensional FEM model, that are more detailed especially where the cement layer is concerned, confirmed the tendencies found Only with respect to the influence of ν_c on axial and hoop stresses did the FEM model give information that could not be provided by the analytical models
From the concepts developed in the previous chapters some guidelines for stem designs and implantation procedures can be derived, as will be discussed in this chapter

It was shown, that all cement and interface stresses are reduced by using an intermediate layer of low Young s modulus and Poisson's ratio It should be borne in mind, however, that a material with a low modulus usually also has low strength properties Silastics, for instance, have a low modulus but are not very strong and almost incompressible (high Poisson's ratio) wh ch makes them rather unsuitable for use as intermediate material Obviously, in the case of acrylic cement, its quality should be optimal From a mechanical point of view the use of an intramedullary plug cleansing before cement insertion and inserting under pressure (see section 1) would therefore be advantageous

In order to reduce the cement and interface stresses at the distal side, the stem length should be kept restricted An adequate length is the one for which the proximal and distal sides are approximately independent in their mechanical behavior, a length that is determined by the coefficients λ_a and λ_t These depend on the structural stiffness of the stem, the bone and the cement layer, that is on the material and geometrical characteristics of the stem, the bone and the intermediate layer This implies for instance that a titanium alloy stem will require a different length compared to a cobalt chromium steel alloy stem, but also, that patients with tiny or osteoporotic bones require stems of different length compared to patients with heavy or dense bones No doubt an indication of the bone quality can be obtained from pre-operative roentgenograms If stems of different sizes were available, the best fitting stem for a specific patient could be chosen pre operatively by using the concepts presented here

On the proximal side the stem should be thick and the material stiff in order to reduce the cement and interface stresses in this region A cement layer of about 2 mm should be retained, however, and this again implies a more 'custom fit' approach, measuring the bone dimensions pre-operatively and choosing an implant from different sizes available
On the distal side the stem should be thin and flexible The requirements for the proximal and distal sides can only be met by using a tapered stem The geometry of the taper can be stud ed by using the FEM beam model, as will be shown in the following example In this example the choice of materials for the stem, entailing conflicting influences on the proxi mal region and the distal and middle regions will also be discussed In order to reduce the stem stresses in the middle region, the stem should be thick and its material flexible

However, the middle region serves no specific purpose in the load transmission process from implant to bone and should be kept restricted as much as possible The effect of the taper shape on the stem stresses will also be discussed in the following example

A specific bone of given properties is assumed (axisymmetric, r_b = 10 mm, r_o = 15 mm, E_b = 2x10^4 N/mm^2) For this bone an adequate stem design will be developed, as an example, using the concepts and methods presented previously
In the proximal region the stem should be as thick as possible, leaving a layer thickness of 2 mm, so that r_s = 8 mm at the proximal side In the first instance the stem material is taken as Co Cr steel (E_s = 2x10^5 N/mm^2) The Young's modulus of the cement is taken as E_c = 2x10^3 N/mm^2, its Poisson's ratio as ν_c = 0 33
In accordance with the results presented in paragraph 6 2, the stem is assumed to loosen upon tension from the cement layer The resulting values for the mechanical characteristics of the proximal side are shown in table 8 I

parameter	unit	value	parameter	unit	value
F_s	Nmm^2	6 43x10^8	P_s	N	4 02x10^7
F_b	Nmm^2	6 38x10^8	P_b	N	7 85x10^6
C_t	N/mm^3	1 79x10^4	C_a	N/mm^2	2 12x10^4
λ_t	mm ^{1}	6 11x10 ^{2}	λ_a	mm ^{1}	5 68x10 ^{2}

table 8 I Values for the characteristic parameters at the proximal side

The length of the proximal side (L_{pr}) is chosen in such a way that the initial load introduction effects are damped out in this region, using the criterion $\lambda_t L_{pr} \geqq \pi/2$ or $\lambda_a L_{pr} \geqq \pi/2$ as discussed in paragraph 5 3 From this it follows $L_{pr} \geqq$ 27 7 mm, we took L_{pr} = 30 mm
As shown in the previous chapter, the distal end of the stem should be thin and flexible, for the extreme distal stem radius we taken r_s = 1 mm Between the distal tip and the end of the proximal region a certain tapered shape has to be designed To determine the length of this part of the stem (L_t), λ_a is used in the first instance, because $\lambda_a < \lambda_t$ As shown in fig 7 11 λ_a varies approximately between 0 060 and 0 035 mm ^{1}, for $1 \leqq r_s \leqq 4$ mm, and between 0 035 and 0 057 mm ^{1} for $4 \leqq r_s \leqq 8$ mm Taking an approximate average value, it follows (with the criterion $\lambda_a L_t \geqq \pi/2$) that $L_t \geqq$ 35 mm, we take L_t = 40 mm to start with This taper shape, and two longer ones (60 and 80 mm) are analysed as to their mechanical performance in the given bone using the FEM beam model
Fig 8 1 shows an example of results stem cement interface stresses $s_{rs}(z)$ and stem stresses $s_{zs}(z)$ on transverse loading, stem cement interface shear stresses $t_s(z)$ and stem stresses [illegible] the taper length of 40 mm has been a good choice where [illegible] region is concerned, but on transverse loading this stem tip is still too stiff For L_t = 60 m[illegible] the stem stresses are somewhat higher, but the distal cement stresses are considerably lower By extending the taper length to 80 mm nothing is gained Taking L_t = 60 mm, two other stem shapes are investigated, as shown in fig 8 2
It is remarkable considering $s_{rs}(z)$ in fig 8 2, that such a seemingly slight difference as between shapes 1 and 2 has so much effect in transverse loading. It should be noted, too, that the stresses on the proximal side do not differ significantly (as is also evident in fig 8 1), because the length of the proximal region was chosen in such a way that both ends of the stem will not influence each other

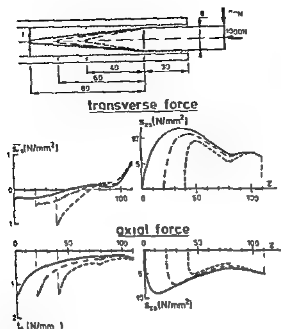

fig 8 1 Stem stresses and stem-cement interface stresses in axial and transverse loading, as calculated with the FEM beam model for three different stem taper lengths

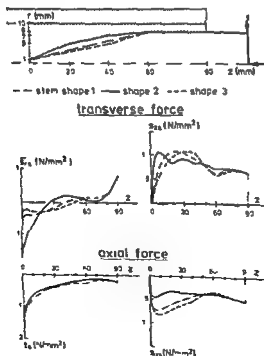

fig 8 2 Stem stresses and stem-cement interf...

Shape 3 is chosen as the best one in this case although there is little difference between 1 and 3 Of course, in reality the abrupt transitions in the taper would have to be somewhat rounded off

Using this shape, the materials choice is further investigated The Young's modulus of the stem is taken as $3x10^5$ N/mm² (simulating ceramics), $2x10^5$ N/mm² (simulating Co-Cr steel) and $1x10^5$ N/mm² (simulating titanium), respectively Some results are shown in fig 8 3 The important aspects of these results can of course be predicted using the approximative formulas As is evident when regarding fig 8 3, the use of ceramics would be advantageous for the proximal cement and interface stresses only, while the use of titanium would be advantageous for all but these stresses (in this case the axial bone stresses are somewhat more natural in addition) Co Cr steel appears to be a reasonable compromise However, if the thickness of the proximal titanium stem could be increased by approximately 20%, while retaining a layer thickness of 2 mm, the proximal cement and interface stresses would be approximately equal to or lower than those for the Co Cr steel stem in the example, as follows from the formulas for F_s and P_s

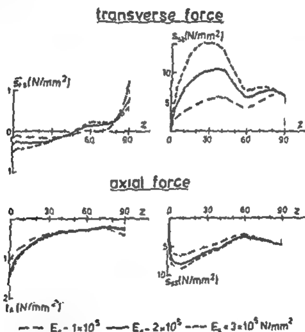

fig 8 3 Stem stresses and stem cement interface stresses in axial and transverse loading, as calculated with the FEM beam model for stem shape no 3 and three different values of Young s modulus of the stem, simulating Co Cr steel, titanium and ceramics
(For ceramics $E_s = 3x10^5$ N/mm² was taken, in reality this value will even be about 30% higher)

It is thus evident that a stem design should (and can) be adapted to the materials applied For instance in the literature 'iso elastic' prostheses are being considered (Morscher et al, 1976) Th[illegible]
bone (E_s [illegible]
the proximal cement The cement and interface stresses in this region would be [illegible]ased by more than 200% in comparison to Co-Cr alloys, which is unacceptable A solution can be found in the application of a proximal stiffener, a steel tube around the proximal stem, whose length can be established by using the formulas for λ_a and λ.

The analyses performed in this example show what can be done to develop an adequate stem design and to evaluate an existing stem design as regards its mechanical performance in a specific bone

Other proposals that are more qualitative can be derived from the studies presented As follows from the stress analyses, the highest stresses in the cement occur close to the stem interface with peak values at the proximal and distal sides Since the strength of the cement as implanted in the bone is many times less than prefabricated (industrial) PMMA, consideration could be given to the use of plastic coated stems thus placing strong material in highly stressed locations As was shown by Ypma *et al* (1979) a coated stem reduces the chances of cement fracture For the same reasons the proximal cement layer could be replaced by a (well fitting) plastic ring to resist the peak stresses here A schematic representation of these concepts is shown in fig 8 4 In this example the cement layer is only very thin over the entire fixation length, giving in addition, less chance of bone necrosis due to thermal damage (see section II) Since the stresses close to the cement bone interface are not so high the use of porous (acrylic) cement could be considered, which would even further reduce the temperatures during the polymerization process (hence also the thermal shrinkage stresses) and would possibly ensure better interlocking with the bone thanks to bone ingrowth The stem shape in fig 8 4 has been chosen in accordance with the previously discussed example The proximal fixation region might be shortened in the course of time due to calcar resorption To prepare for this effect, this region could be designed somewhat longer

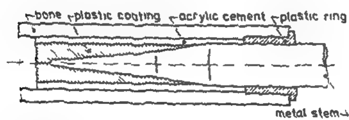

fig 8 4 A schematic concept for an idealized intramedullary fixation system using plastic coating and a plastic ring in highly stressed regions

In the examples treated here only the flexural and compressional stiffness aspects of the stem were discussed In an actual design these stiffness values have to be translated into cross-sectional geometry *Since the stem on the proximal side the* [illegible]

CHAPTER NINE

DISCUSSION

The models applied here were intended to describe the intramedullary bone prosthesis structure in a qualitative sense, to find its characteristic parameters and to evaluate the relations between these parameters and the mechanical behavior

As has been demonstrated, simplified (especially analytical) models have better options for the development of such general, fundamental concepts than detailed, geometrically refined three dimensional FEM models Of course, these refined models are in principle better suited to calculate actual stress values in an absolute sense However, bone prosthesis structures have many complicated properties which can as yet hardly be described mathematically and which do not so much affect their mechanical behavior in general but very much affect the local stress distribution, as was shown in chapter 6

On the other hand, however, simplified models can usually only be developed for such complicated structures when more sophisticated numerical analyses (and experiments) can serve as references In the analyses presented here, analytical models were developed on the basis that the stem and the bone separately behave by approximation in accordance with beam theory For other than intramedullary bone prosthesis structures a suitable (relatively simple) theory might not be so easily found In that case numerical analyses are all that remain However, for instance as regards the tibial plateau of the artificial knee joint, too approximative analytical theories can be applied, as was shown by Haemmerle *et al* (1977)

Owing to the qualitative character of the analyses, no comparison was made between calculated stress values and strength data of the materials and the interfaces It is difficult, too, to find reliable strength criteria for cement and bone, since so much depends on surgical variables and individual differences It would be realistic to assume that where the bone is concerned, the stress pattern should be as 'natural as possible In this respect the radial transverse stresses and the shear stresses at the cement bone interface are quite unnatural for the bone and should be kept restricted as much as possible

The order of magnitude of the maximal stress values found in the cement is such that cement failure cannot be excluded This is also true for thermal stresses caused by shrinkage immediately following the polymerization process, as shown in paragraph 6 1 These stresses are maximal in the middle of the cement mass and cracks might thus develop there and not be detected during surgery Thanks to stress relaxation these locked in' stresses will have no influence on the long term mechanical behavior of the structure (unless, of course, the damage was already done directly postoperatively)

Using the fundamental concepts developed here, analyses presented in the literature can be evaluated to some extent As was shown in paragraph 5 5 , the intramedullary fixation structure is not very well suited for analyses using two dimensional models If no side plates are applied in the model, a sandwich construction is in fact analysed in which unrealistically high shear stresses will occur (McNeice *et al*, 1975, 1976, Andriacchi *et al*, 1975, Kwak *et al*, 1979) Furthermore, slip at the stem cement (or cement bone) interface will cause the overall flexural stiffness of such a model to be reduced drastically, resulting in unrealistically high stem and bone stresses

A two-dimensional FEM model using side plates was presented by Svensson *et al* (1977) They concluded from their analysis that the use of a heavier prosthesis stem may be

beneficial, as we have seen, this is only true for the proximal side, provided a cement layer of adequate thickness is retained Their remark that stem and cement material properties do not influence the critical stress values can not be correct

The detailed three dimensional FEM models of Rohrle *et al* (1977, 1979) and Scholten *et al* (1978) were mainly used for comparative studies on different prostheses designs They varied the stiffness of the stem material and reached the same conclusions as to the proximal side as were found here

A more extensive parametric analysis was carried out by Crowninshield *et al* (1979), with their three-dimensional model of an implanted hip endoprosthesis They varied the Young s moduli of the stem and the cement, the stem length and the stem thickness Generally speaking, the tendencies of their results agree perfectly with the results presented here Although theirs is a profound and sophisticated study, the results are rather specific, owing to the empirical character of such numerical analyses They conclude that measures to be taken in order to minimize the stresses in cement or stem are in conflict As was shown here this is not true in general, as can be established if the proximal and distal regions are treated separately Where it is true, optimal dimensions can usually be calculated They advise reducing Young's modulus of the cement (which is indeed advantageous for all stress components in the cement and will hardly affect the stem stresses) to increase the Young's modulus of the stem (only on the proximal side, which follows clearly from their results, too), increasing the stem thickness (which is again only advisable for the proximal side and should not be done in general, since an adequate cement layer (at least 2 mm) should be retained on the medial side) and increasing the stem length (which again should not be done in general, as shown here the 'optimal' length depends also on other parameters of the structure and the length should not be increased beyond this optimal value)

Since by using approximative formulas as derived here (together with such simple methods as the FEM beam model), the mechanical behavior of the structure can be adequately described in the general sense, more detailed studies could be conducted by analysing more local phenomena, especially in the cement bone interface region, using the approximative general results as boundary conditions and also using radiographical and histological data As discussed in paragraph 6 4 , especially taking bone remodeling phenomena into account would be of interest

CHAPTER NINE

DISCUSSION

The models applied here were intended to describe the intramedullary bone prosthesis structure in a qualitative sense, to find its characteristic parameters and to evaluate the relations between these parameters and the mechanical behavior
As has been demonstrated, simplified (especially analytical) models have better options for the development of such general, fundamental concepts than detailed, geometrically refined three dimensional FEM models Of course, these refined models are in principle better suited to calculate actual stress values in an absolute sense However, bone prosthesis structures have many complicated properties which can as yet hardly be described mathematically and which do not so much affect their mechanical behavior in general but very much affect the local stress distribution, as was shown in chapter 6
On the other hand, however, simplified models can usually only be developed for such complicated structures when more sophisticated numerical analyses (and experiments) can serve as references In the analyses presented here, analytical models were developed on the basis that the stem and the bone separately behave by approximation in accordance with beam theory For other than intramedullary bone prosthesis structures a suitable (relatively simple) theory might not be so easily found In that case numerical analyses are all that remain However, for instance as regards the tibial plateau of the artificial knee joint, too, approximative analytical theories can be applied, as was shown by Haemmerle *et al* (1977)

Owing to the qualitative character of the analyses, no comparison was made between calculated stress values and strength data of the materials and the interfaces It is difficult, too, to find reliable strength criteria for cement and bone, since so much depends on surgical variables and individual differences It would be realistic to assume that where the bone is concerned, the stress pattern should be as 'natural' as possible In this respect the radial transverse stresses and the shear stresses at the cement bone interface are quite unnatural for the bone and should be kept restricted as much as possible
The order of magnitude of the maximal stress values found in the cement is such, that cement failure cannot be excluded This is also true for thermal stresses caused by shrinkage immediately following the polymerization process, as shown in paragraph 6 1 These stresses are maximal in the middle of the cement mass and cracks might thus develop there and not be detected during surgery Thanks to stress relaxation these 'locked in' stresses will have no influence on the long term mechanical behavior of the structure (unless, of course, the damage was already done directly postoperatively)

Using the fundamental concepts developed here, analyses presented in the literature can be evaluated to some extent As was shown in paragraph 5 5 , the intramedullary fixation structure is not very well suited for analyses using two dimensional models If no side plates are applied in the model, a sandwich construction is in fact analysed in which unrealistically high shear stresses will occur (McNeice *et al*, 1975, 1976, Andriacchi *et al*, 1975, Kwak *et al*, 1979) Furthermore, slip at the stem cement (or cement bone) interface will cause the overall flexural stiffness of such a model to be reduced drastically, resulting in unrealistically high stem and bone stresses
A two-dimensional FEM model using side plates was presented by Svensson *et al* (1977) They concluded from their analysis that the use of a heavier prosthesis stem may be

beneficial, as we have seen, this is only true for the proximal side, provided a cement layer of adequate thickness is retained Their remark that stem and cement material properties do not influence the critical stress values can not be correct
The detailed three-dimensional FEM models of Rohrle *et al* (1977, 1979) and Scholten *et al* (1978) were mainly used for comparative studies on different prostheses designs They varied the stiffness of the stem material and reached the same conclusions as to the proximal side as were found here
A more extensive parametric analysis was carried out by Crowninshield *et al* (1979), with their three-dimensional model of an implanted hip endoprosthesis They varied the Young's moduli of the stem and the cement, the stem length and the stem thickness Generally speaking the tendencies of their results agree perfectly with the results presented here Although theirs is a profound and sophisticated study, the results are rather specific, owing to the empirical character of such numerical analyses They conclude that measures to be taken in order to minimize the stresses in cement or stem are in conflict As was shown here, this is not true in general, as can be established if the proximal and distal regions are treated separately Where it is true, optimal dimensions can usually be calculated They advise reducing Young's modulus of the cement (which is indeed advantageous for all stress components in the cement and will hardly affect the stem stresses) to increase the Young's modulus of the stem (only on the proximal side, which follows clearly from their results, too), increasing the stem thickness (which is again only advisable for the proximal side and should not be done in general, since an adequate cement layer (at least 2 mm) should be retained on the medial side) and increasing the stem length (which again should not be done in general, as shown here the 'optimal' length depends also on other parameters of the structure and the length should not be increased beyond this optimal value)

Since by using approximative formulas as derived here (together with such simple methods as the FEM beam model), the mechanical behavior of the structure can be adequately described in the general sense, more detailed studies could be conducted by analysing more local phenomena, especially in the cement bone interface region, using the approximative general results as boundary conditions and also using radiographical and histological data As discussed in paragraph 6 4, especially taking bone remodeling phenomena into account would be of interest

APPENDIX A

RESULTS OF THE THREE DIMENSIONAL FEM CALCULATIONS

The following graphs show the values of the stress 'amplitudes', $\hat{\sigma}_r$, $\hat{\sigma}_t$, $\hat{\sigma}_z$, $\hat{\tau}_{rt}$, $\hat{\tau}_{rz}$, τ_{tz} and the equivalent stress σ_{eq} (maximal value) as functions of z, for $r = r_s$ and $r = r_b$ (lines 1 and 2 3 and 4 respectively), calculated with the three dimensional FEM model, for two loading cases (fig A 1) *For the stem only $\hat{\sigma}_z$ has been drawn, since the other stress components have insignificant values in comparison It should be borne in mind that $\hat{\tau}_{rt}$ and $\hat{\tau}_{tz}$ are zero* for the axial loading case and therefore have not been drawn also

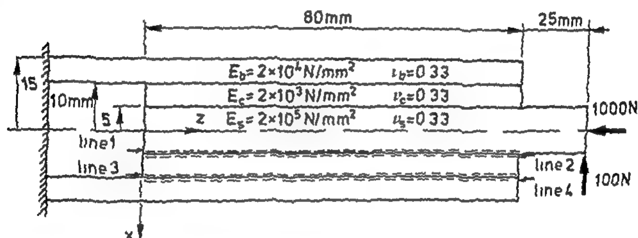

fig A 1 Characterization of the structure for which the stress amplitudes are given in the following graphs

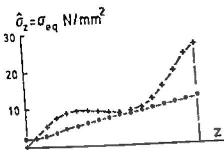
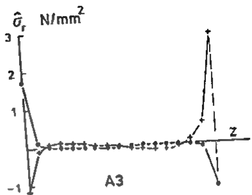
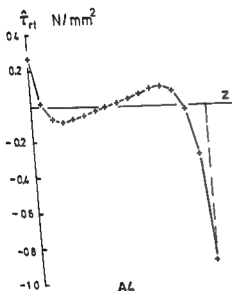


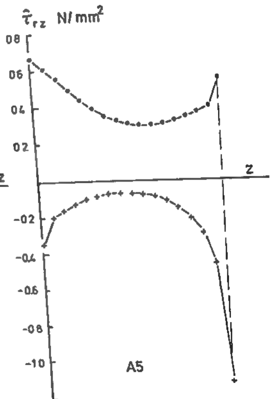
Three stress components are continuous across the interface ($\hat{\sigma}_r$, $\hat{\tau}_{rt}$ and $\hat{\tau}_{rz}$), thus equal in both materials These components are referred to as interface stresses and the values shown are those for the cement (in the calculations the continuity is not always exactly fulfilled, Huiskes, 1977)
The following line codes are used



Axial Force (Z)



\+ + + Transverse Force (X)



The dots refer to the nodal point values

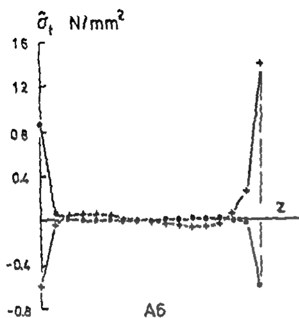


Fig A 2 stem stresses, line 1 ($r = r_s$), figs A 3 through A 5 stem cement interface stresses, line 2 ($r = r_s$), figs A 6 through A 9 *cement stresses, line 2 ($r = r_s$), figs* A 10 through A 13 cement stresses, line 3 ($r = r_b$), figs A 14 through A 16 cement bone interface stresses line 3 ($r = r_b$), figs A 17 through A 20 bone stresses line 4 ($r = r_b$)

fig B 2 Different cross sectional geometries of a cement slice, (a) axisymmetric, (b) rectangular and (c) arbitrary

where γ_s is the circumference of the stem $\bar{\delta}_a$ the average layer thickness
For $\rho = 0.5$ ($r_b - r_s = 5$ mm) formulas (B 1) and (B 2) gave good agreements with FEM calculations. For higher ρ the accuracy will be even better, for smaller ρ the accuracy will decrease
Formula (B 3) is an extrapolation of (B 1) and (B 2) and should only be expected to give reasonable results if the layer is thin and the variation in thickness restricted When formula (B 3) is used to approximate C_a for circular geometry, for $\rho = 0.5$ an under estimation of about 30% results compared to (B 1), for $\rho = 0.7$ agreement is quite reasonable

Stiffness against transverse loading

A slice dz of the structure is shown in fig B 3 The bone and the stem are assumed to be rigid Plane strain state is assumed in the cement layer (for plane stress state, see Huiskes and Schouten 1979) The results for different cases are summarized in table B 1

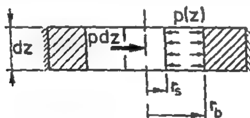

fig B 3 A slice of the structure in transverse loading

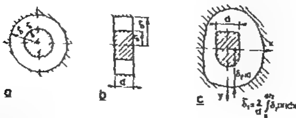

fig B 4 Different cross sectional geometries of a cement slice (a) axisymmetric, (b) rectangular and (c) arbitrary

THE STRUCTURAL STIFFNESS OF A SLICE OF BONE CEMENT

In the beams on elastic foundation models the Winkler hypothesis is applied to the acrylic cement layer which means that the layer is assumed to consist of an infinite number of linear elastic springs with spring constants C_a (N/mm²) for axial loading and C_t (N/mm²) for transverse loading Approximative formulas for C_a and C_t can be derived using analytical and FEM models These analyses have been described in Huiskes and Schouten (1979), in this appendix only a summary of the results is given

Stiffness against axial shear

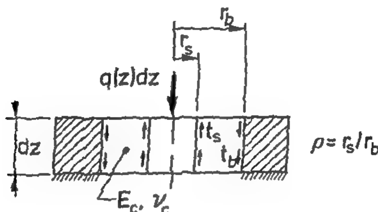

fig B 1 A slice of the structure in axial loading

A slice dz of the structure is shown in fig B 1 The bone and the stem are assumed as rigid The Winkler hypothesis in this case implies that only shear stress in the axial direction is present in the cement layer For circular geometry it follows (fig B 2 a) that

$$C_a \approx - \frac{\pi E_c}{(1+\nu_c)\ln\rho} \quad (\rho = r_s/r_b) \tag{B 1}$$

for rectangular geometry (plane model) (fig B 2 b) we have

$$C_a \approx \frac{dE_c}{(r_b-r_s)\,(1+\nu_c)} \tag{B 2}$$

and for arbitrary geometry (fig B 2 c)

$$C_a \approx \frac{1}{2}\frac{\gamma_s E_c}{\delta_a(1+\nu_c)} \tag{B 3}$$

(B 8) and (B 9) and will presumably give reasonable results if the stem geometry is not too irregular If formula (B 10) is used to approximate C_t in circular geometry, the agreement with the FEM results is even better than when formula (B 4) is used, formula (B 10) is, however, somewhat inconvenient, since for circular geometry

$$\delta_t = \frac{1}{2} r_b \left\{ \sqrt{(1-\rho^2)} + \frac{1}{\rho} \arcsin\rho - \frac{\pi}{2}\rho \right\}$$

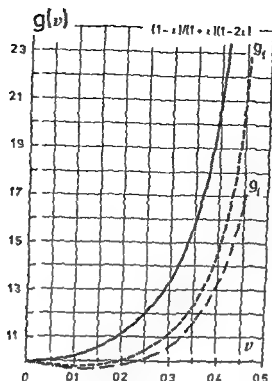

fig B 5 Three functions of ν_c, used in the expressions for C_t

	stem cement interface rigidly connected		stem cement interface loose and no friction	
circular geometry (1) (fig B 4 a)	$5.3E_c g_f(\nu_c)\,(0.24+\frac{\rho}{1-\rho})$	(B 4)	$1.9E_c g_l(\nu_c)\,(0.24+\frac{\rho}{1-\rho})$	(B 5)
rough approximation	$\frac{4E_c(1-\nu_c)\rho}{(1-\rho)(1+\nu_c)(1-2\nu_c)}$	(B 6)	$\frac{2E_c(1-\nu_c)\rho}{(1-\rho)(1+\nu_c)(1-2\nu_c)}$	(B 7)
rectangular geometry (fig B 4 b), uni axial strain assumed	$\frac{2dE_c(1-\nu_c)}{(r_b-r_s)(1+\nu_c)(1-2\nu_c)}$	(B 8)	$\frac{dE_c(1-\nu_c)}{(r_b-r_s)(1+\nu_c)(1-2\nu_c)}$	(B 9)
'arbitrary' cross section (fig B 4 c)	$\frac{2.5dE_c(1-\nu_c)}{\delta_t(1+\nu_c)(1-2\nu_c)}$	(B 10)	$\frac{1.25dE_c(1-\nu_c)}{\delta_t(1+\nu_c)(1-2\nu_c)}$	(B 11)

SECTION FOUR

CONCLUSIONS AND CLOSING REMARKS

In view of the probable ranges in the parameter values on the one hand and the ranges in thermal necrosis threshold levels on the other, it can be concluded from the analyses that thermal necrosis in the cortex of the bone during fixation of intramedullary stems is impro bable, that the incidence of thermal necrosis in general cannot be excluded and that in specific (predictable) circumstances it will certainly occur

The heat conduction process and the temperature values are significantly influenced by the d mensions of the bone Hence when heat conduction phenomena or their consequences as regards thermal necrosis (for instance in histological analyses), are studied in smaller animal models, the results cannot simply be translated to human circumstances In this respect it is found to be rather unlikely that the cortical bone necrosis reported by Feith (1975 see section II) in his rabbit experiments was mainly caused by thermal necrosis By combining his experimental results with those of the analyses presented here, the hypothesis evolves that the heat of polymerizing has an indirect effect, by influencing the cell toxic actions of the monomer, rather than a direct necrotic effect on the bone tissue

In order to reduce the temperatures several precautions can be taken Adding 'heat sinks' as radiopaque fillers ($BaSO_4$ or ZrO_2) to the powder has but little effect Pre cooling of the implant and the cement for instance by 10°C is also of little effect while more drastic cooling will probably prejudice the polymerization process More influence is exerted by the addition of an aqueous gel to the cement mixture (porous cement) and by increasing the powder to-liquid ratio although these measures can only be applied in a limited sense, since in this case too, the cement properties especially its strength, may suffer Decreasing the polymerization rate has a moderate influence, but when the auto-acceleration effect is drastically surpressed the maximal temperatures will be significantly reduced A quite effective and useful measure is the cooling of the operation region before cement insertion and during the polymerization process The effectiveness of these measures can easily be evaluated by using the graphs presented in chapter 9 of section II
The surgeon furthermore can effectively reduce the temperatures by limiting the amounts of cement used In this respect it should be noted that acrylic cement in fact fulfills two different functions adapting the smooth implant to the irregular implant bed and filling spaces The latter function could be provided by pre polymerized materials as well, by applying plastic fillers of different dimensions and shape and plastic coated implants In that case only little self curing acrylic cement would have to be used, thus reducing the bone temperatures and the chances of thermal tissue damage

Stress analyses

By applying beams-on-elastic foundation theory to a simplified, general model of intra medullary fixation structures (using results of *experimental and th*

By applying fundamental gener

The analyses, discussed in the previous sections, provide fundamental data from which guidelines for prosthesis designs, implantation procedures and acrylic cement composition can be derived. Obviously, the aspects treated here are not the only ones that provide guidelines; others, too, affect the system performance and the designs and procedures ultimately chosen will usually be based on compromises between criteria of biological, mechanical, chemical and surgical origin In this respect the recommendations resulting from the analyses presented here are partial in character and should therefore certainly not be regarded as prescriptions, but merely as guidelines. It is evident, however, that any compromise will have more chances of succes when its various (possibly conflicting) criteria are in themselves firmly based on fundamental data.
Conclusions have been stated at different stages in sections II and III; in the following pages some of them, that may be of interest to orthopedic surgeons, will be discussed in more general terms.

Heat generation and conduction analyses

The heat generation and conduction process in polymerizing acrylic cement and the mate-rials adjacent to it can be described mathematically with quite reasonable accuracy by applying theories of heat conduction In this way the temperatures as a function of time in a given bone prosthesis structure during and after polymerization can be predicted by approximation. The parameters that describe the thermal properties of the relevant materials, hat have to be used in the calculations, can be estimated on the basis of literature data. In some cases, especially as regards the bone tissue, only a range of probable values can be found.

The cement-bone interface is a region rather than a smooth, well defined area of contact, which has a certain heat-flow resistance Consequently, a steep temperature drop will occur over a relatively small distance and hence the 'cement bone-interface temperature' is an undefined quantity, a fact to which the scatter in experimental data as reported in the iterature can, at least partly, be ascribed The thermal conductivity of the interface greatly nfluences the maximal bone-temperature values and the penetration depth of the heat into he bone. Anything that can be done to reduce the interface conductivity also reduces the chances of bone necrosis, and from this point of view cleansing of the implant bed prior to cement insertion would not be advantageous (contrarily, however, to criteria of mechanical nterface strength).

During acetabular-cup fixation, the temperatures occurring in the bone adjacent to the cement are higher than those in the case of intramedullary (metal) stem fixation The maximal values greatly depend on the amounts of cement used and on the (macro) geometry of the bony implant bed, which should be smooth and concave When acrylic cement is pressed against trabecular bone, the tips of trabeculae surrounded by cement may reach temperatures up to 70°C, at which instant thermal necrosis is a certainty, in view of the iterature data on thermal necrosis threshold levels
Apart from these trabecular tips, the bone adjacent to the cement may, in general, reach [illegible] 50 to 60°C while a bone layer of 1 to 4 mm [illegible] ng on the specific circumstances In this range, he occurrence of thermal necrosis greatly depends on the time of exposure For an exposure ime of 30 sec., thermal threshold levels for cell necrosis between 50 and 55°C have been eported in the literature.

length can be evaluated also by applying the methods presented here

A more or less optimal mechanical performance of the bone prosthesis structure depends on an adequate set of structural parameter values This means that when some of these parameters are given quantities the others should be adapted to guarantee an adequate stress distribution On the one hand this implies that, for instance prostheses made of titanium alloys, with lower material stiffness, require different stem designs than those fabricated with cobalt chromium alloys or ceramics, on the other hand it is evident that patients with small bones require different prostheses than those having heavy bones It would thus be recommendable if several sizes of a certain prosthesis were available and a choice was made pre-operatively, on the basis of roentgen measurements, taking into account the concepts developed here (simple and rapid evaluation methods as the FEM beam model, too, could be useful in this procedure)

As mentioned previously, the highest cement stress values occur on the proximal and distal sides close to the stem cement interface Since acrylic cement, as present in the bone, is many times weaker than industrial PMMA, it would be advantageous to use pre polymerized plastic in these regions, for instance by applying plastic coated stems and plastic rings at the proximal side

If a specific hip endoprosthesis is placed in valgus then, apart from a possible influence on the joint loading, the cement mantle thickness at the medial, proximal side is increased, so that the unphysiological radial and shear stresses on the cement bone interface as well as the hoop stresses in the bone at the calcar region are reduced It is remarkable that Bocco *et al* (1978) (see section I) found a significant reduction in the incidence of calcar resorption after placing the prostheses in valgus *position* Especially these remodeling and resorption phenomena including [illegible]
present important an [illegible]
calling for detailed k[illegible]
tissue changes into a[illegible] impossible to develop a model adequately refined to this end in a local sense which at the same time incorporates the whole structure, the concepts and methods developed here provide a good basis for carrying out such analyses in two steps, using the rough overall stress distribution as boundary conditions for a refined model of a detail of the structure

detailed and accurate stress analyses of intramedullary fixation structures Although useful in studying tendencies in a relative sense, provided certain precautions have been taken in the process of modeling, the visual apparent agreement between such a model and, for instance an X ray of the structure, is often misleading
The mechanical conditions at the stem cement contact area, that may slip and cannot transfer tensile stresses, have only a moderate influence on the mechanical performance of the structure in general, but a pronounced effect on the local stress distribution in the intermediate layer (the cement) and at the interfaces Hence, in detailed stress analyses these phenomena should certainly be taken into account
Composite beam theory, as often used in the literature, is appropriate for the middle region only, to calculate stresses in the axial direction Where the cement layer is concerned, however, the stresses in this region are quite insignificant compared to those in the proximal and distal regions
Based on the same concepts as the beams-on elastic foundation model (essentially assuming that both the bone and the stem behave in accordance with linear beam theory and the cement mantle as an elastic layer), a Finite Element Methods (FEM) beam model can be developed This model can take nonhomogeneous properties of the structure into account and may serve as a rapid, inexpensive evaluation method for the mechanical performance of specific stem designs in given bones under different circumstances

The maximal stem stresses occur, roughly speaking, in the middle region, the maximal cement and interface stresses at the proximal and distal sides, in both cases at the stem cement interface (radial and shear stresses) The axial stresses in the bone are lower com pared to the 'natural' case, at the proximal side (the calcar region in the case of hip endoprostheses) quite unphysiological radial and shear stresses occur at the cement bone inter face as well as hoop stresses in the bone
Immediately following the polymerization process, the cooling acrylic cement will shrink around the stem, leaving locked in stresses in the mantle These stresses will gradually relax, as can be concluded from relaxation tests, decreasing by about 75% in 7 days However, during the operation the generated hoop stresses may cause the cement mantle to fracture, as can be concluded from approximative calculations, using data on temperature distributions as evaluated in section II These stresses are maximal in the middle of the cement mantle, so that tiny cracks may remain undetected

In using the fundamental concepts provided by the beams on elastic foundation analysis and applying the FEM beam model, guidelines for stem designs and implantation procedures can be developed These guidelines are derived on the assumption that, although the causes of bone remodeling phenomena are uncertain as yet a joint replacement will have less chances of failure if the stresses in the stem and the cement, as well as the unphysiological stress components in and on the bone are reduced, or at least smoothened, as much as possible
From the approximative formulas it follows that on the proximal side the flexural and com pressional stiffness of the stem should be as high as possible, which implies a thick stem, but retaining a cement layer of adequate thickness In the case of the hip endoprosthesis the layer thickness should be around 2 mm On the distal side the stem should be as flexible as possible, the intermediate layer as thick as possible Together these requirements point to a tapered stem The shape of the taper should not be an arbitrary one since it has a marked influence on the cement and stem stresses Using the FEM beam model, this shape can be more or less optimized
The length of the stem, too, has an optimal value that depends on the specific stem material properties, its shape, the cement properties and the properties of the bone An adequate

SUMMARY

It was the object of the studies described in this work to provide general, fundamental concepts on some aspects of human joint replacement and the performance of artificial joints in the body
The work is divided into four sections of which the first discusses joint replacement and bone prosthesis structures in general In section II analyses of the process of heat generation and conduction in self curing acrylic cement, as used for implant fixation, are presented with the object of establishing the chances of thermal bone tissue necrosis and evaluating pre cautions that can be taken to prevent it. Section III is devoted to stress analyses of intra medullary fixation structures under loading, with the object of determining the characteristic mechanical parameters of such structures, evaluating their influences on the mechanical performance and providing guidelines for prosthesis designs and implantation procedures
In section IV some conclusions and recommendations, as reached on the basis of the analyses, are once more briefly discussed in general terms

Section I

Chapter 1 outlines some general aspects of artificial joint replacement The surgical procedure, general requirements for implant designs and the features of commercially available types are briefly discussed Furthermore, the physiological joint loading, the properties of acrylic bone cement and bone remodeling phenomena are briefly described As in the greater part of this work, the data are mainly focussed on the artificial hip joint
Chapter 2 gives an overview of a selection from the literature on postoperative complications, especially artificial joint loosening and fracture
The objects and methods of the analyses fully treated in sections II and III, are discussed in chapter 3
Besides providing data to be used in sections II and III and outlining the framework for the studies presented this section may serve as an introduction for those unacquainted with human joint replacement procedures

Section II

After a short introduction in chapter 1, a review of the literature on previous work as regards temperatures in self curing acrylic cement and its adjacent materials in bone-prosthesis structures is given in chapter 2 In chapter 3, too, a literature review is presented, this time as regards available data on thermal threshold levels of bone tissue necrosis
To evaluate the time dependent temperatures in the acrylic cement, the implant and the bone during implant fixation, theoretical models are applied, the principles of which are presented in chapter 4 Parameter values that describe the thermal materials properties to

be used in the analyses are estimated on the basis of an extensive literature review, as discussed in chapter 5

The suitability of the method of analysis and the estimated parameter values are verified by simulating laboratory experiments, published in the literature, and by comparing calculated with measured temperatures, as shown in chapter 6

In chapter 7 a general model of an intramedullary fixation system is analysed Time dependent temperatures in the cement mantle, the prosthesis stem and the cortex of the bone are calculated In an extensive parametric analysis, the influences of the relevant geometrical, thermal and compositional properties of the system on the temperature values are evaluated The effects of cement quantities used, implant dimensions and vascular cooling are discussed Furthermore, the relevancy of using animal models to study thermal damage phenomena in this respect for human circumstances is investigated By comparing predicted bone temperature values with thermal damage threshold levels, the chances of bone tissue necrosis are estimated On combining results with those of relevant histological studies published in the literature, a hypothesis on the principal causes of the adverse side effects of acrylic cement evolves

Chapter 8 discusses an analysis of the process of heat generation and conduction during acetabular cup fixation Here, too, the occurrence of thermal damage to the bone at different locations is estimated

In chapter 9 the effectiveness of precautions that can be taken to reduce the temperatures are investigated Specific recommendations are made and simple graphs are presented for a rapid first order evaluation of the effect of several temperature reducing measures

Section III

After a short introduction in chapter 1, a review of the literature on stress analyses of bone prosthesis structures is presented in chapter 2 It is established that the available data on the mechanical performance of intramedullary fixation structures lack a general, fundamental basis To provide for this a simplified general model is analysed using different numerical and analytical methods This model is introduced in chapter 3 Results of strain gauge experiments on a cadaveric femur discussed briefly in chapter 4 serve as references for the analyses Different methods of analyses are applied and compared in chapter 5 Simple formulas are derived that approximate the most important stresses in the materials of the structure and at the contact regions as a function of the essential structural parameters A simple computer model is developed that can be used for inexpensive and rapid first-order evaluation of the mechanical performance of specific prosthesis stem designs in given bones The models used are based on assumptions and simplifications as regards the real structure, and the possible influences of neglected aspects are discussed in chapter 6 Attention is given to the occurrence of thermal locked in stresses in the cement mantle caused by shrinkage following the polymerization process the mechanical conditions of the stem cement and the cement bone contact regions (interfaces) more arbitrarily shaped stems and bones, the influences of torsional loading on the prosthesis and a few others

Chapter 7 discusses the influences of the characteristic parameters of the stem, the bone and the intermediate layer on the structural performance on the basis of parametric analyses, using the fundamental concepts derived in chapter 5 combined with the different computer models

In chapter 8 guidelines for prosthesis designs and implantation procedures as follow from ... example it is shown ... proxi

mative formulas and the rapid evaluation computer model

be used in the analyses are estimated on the basis of an extensive literature review, as discussed in chapter 5

The suitability of the method of analysis and the estimated parameter values are verified by simulating laboratory experiments, published in the literature, and by comparing calculated with measured temperatures, as shown in chapter 6

In chapter 7 a general model of an intramedullary fixation system is analysed Time dependent temperatures in the cement mantle, the prosthesis stem and the cortex of the bone are calculated In an extensive parametric analysis, the influences of the relevant geometrical, thermal and compositional properties of the system on the temperature values are evaluated The effects of cement quantities used, implant dimensions and vascular cooling are discussed Furthermore, the relevancy of using animal models to study thermal damage phenomena in this respect for human circumstances is investigated By comparing predicted bone temperature values with thermal damage threshold levels, the chances of bone tissue necrosis are estimated On combining results with those of relevant histological studies published in the literature, a hypothesis on the principal causes of the adverse side effects of acrylic cement evolves

Chapter 8 discusses an analysis of the process of heat generation and conduction during acetabular cup fixation Here, too, the occurrence of thermal damage to the bone at different locations is estimated

In chapter 9 the effectiveness of precautions that can be taken to reduce the temperatures are investigated Specific recommendations are made and simple graphs are presented for a rapid first order evaluation of the effect of several temperature reducing measures

Section III

After a short introduction in chapter 1, a review of the literature on stress analyses of bone prosthesis structures is presented in chapter 2 It is established that the available data on the mechanical performance of intramedullary fixation structures lack a general, fundamental basis To provide for this a simplified, general model is analysed using different numerical and analytical methods This model is introduced in chapter 3 Results of strain gauge experiments on a cadaveric femur, discussed briefly in chapter 4, serve as references for the analyses Different methods of analyses are applied and compared in chapter 5 Simple formulas are derived that approximate the most important stresses in the materials of the structure and at the contact regions as a function of the essential structural parameters A simple computer model is developed that can be used for inexpensive and rapid first-order evaluation of the mechanical performance of specific prosthesis stem designs in given bones The models used are based on assumptions and simplifications as regards the real structure, and the possible influences of neglected aspects are discussed in chapter 6 Attention is given to the occurrence of thermal locked in stresses in the cement mantle caused by shrinkage following the polymerization process, the mechanical conditions of the stem cement and the cement bone contact regions (interfaces), more arbitrarily shaped stems and bones, the influences of torsional loading on the prosthesis and a few others

Chapter 7 discusses the influences of the characteristic parameters of the stem, the bone and the intermediate layer on the structural performance on the basis of parametric analyses, using the fundamental concepts derived in chapter 5 combined with the different computer models

In chapter 8, guidelines for prosthesis designs and implantation procedures, as follow from the analyses, are given Several recommendations are made and in an example it is shown how, for a specific given bone, an adequate stem design can be developed using the approximative formulas and the rapid evaluation computer model

Preface

My teacher the late Wilhelm Anthonsen encouraged my interest in orthopaedic surgery for the treatment of the sequelae of neuromotor diseases This interest was further encouraged by a stimulating and extended visit in 1970 to Sheffield to Mr W J W Sharrard whose consistent application of the principles of muscle imbalance and the deforming forces has been an inspiration for so many orthopaedic surgeons Next came a stay in Toronto in 1971 with Professor R B Salter and Mr Norris Carroll Mr John Hall and Mr Mercer Rang where support was gained for a view of the dynamics of the hip not generally accepted at that time I am very grateful for the kindness extended and the instruction offered on these study tours

I wish to thank the Guildal Foundation and The Society and Home for Cripples Copenhagen for economic support for my travels

Encouragement to undertake these journeys and stimulating and provocative discussions of the orthopaedic problems in the treatment of patients with neuromotor disease were provided by Dr med Sven Brandt Lecturer Dr med Knud Jansen and Dr med Jorgen Saugmann Jensen who are thanked for their helpful contributions

Uncertainty as to the significance of the musculature for the stability of the hip was the soil which nourished the ideas underlying the present study These ideas started to germinate in 1969 in the course of the weekly clinics in the Outpatient Department for Handicapped Children the Rigshospital under the leadership of Professor Preben Plum I would like to thank him not only for his professional and personal stimulus but also for his never failing interest in the well being of the handicapped I like others owe Professor Plum a debt of gratitude for his contribution

The study was completed during my appointment in the Department of Orthopaedic Surgery U the Rigshospital from 1973 to 1978 I am very grateful to the head of the department Professor C C Arnoldi for the independent working conditions provided and for his support and criticism of the thesis and also because Professor Arnoldi has shown in writing and practice that the handicapped children must always have our support even though other important tasks also must be solved

The work could not have been completed without the splendid service provided by the personnel of the X ray archives and the secretaries at Ebberodgård the Children s Hospital in Vangede the Orthopaedic Hospital and the Rigshospital

The photographic department and the drawing office of the Rigshospital are also thanked for their professional assistance

The statisticians Dr J S Olsen and J Nyboe Actuary are thanked for discussions and advice on the statistical analysis of the results

H Cowan B Sc is thanked for the translation into English and for helpful linguistic discussions

The Danish Cerebral Palsy Foundation the Danish Medical Research Council and the P G Foundation have provided economic support in various phases of the work

The study was concluded in November 1977

Contents

The extreme shows us
the way to the norm

Hypothesis

In the growing child, there is a connection between the position of the head of the femur in relation to the acetabulum, and the function of the surrounding muscles In particular, it is the balance between the adductors and the abductors of the hip that is of significance for the stability of the hip in the frontal plane

Chapter I

Introduction

An attempt to understand the principles for the origin of the various deformities and their interrelations in children with neuromotor disturbances resulted in a paper on the static and dynamic problems when the patient is observed from the side (*Reimers* 1973b) The condition originally studied was spastic cerebral palsy but it was found that the principles demonstrated in the paper corresponded fully to what is known in the case of other although less deforming diseases

We know that the bones and joints are moulded by the influence of the surrounding musculature (*Wolff's Law*) and there is no reason to suppose that the bones and joints are concerned whether the cause of an altered muscular influence is of a neurogenic or of a primarily myogenic nature When therefore we wish to elucidate in the frontal plane some of the static and dynamic problems of the hip joint in childhood we may as well employ as a material children with pronounced deformities since by a study of the extreme we may learn something of the minor deviations from the norm

McKibbin (1970) stated that in congenital dislocation of the hip *a sharp distinction should be drawn between the factors responsible for the initial displacement and those influencing the further progression* This study will be concerned with an examination of the latter factors

The hip in myelomeningocele

To form an impression of what is already known on the subject of this study we may examine the hip in myelomeningocele as this condition gives a good picture of the significance of the surrounding muscles for the stability of the hip

Sharrard's study from 1964 has familiarized us with the segmental innervation of the musculature of the hip and lower limbs We may compare the normal picture with that from for example the study by *Carroll & Sharrard* (1972) of [illegible] hip joints in children with myelomeningocele which showed that when there was a nerve lesion at the level of L_I to L_{IV} the hip was found dislocated at birth in 40 per cent and 2 to 3 years later a further 15 per cent had developed dislocation If the nerve lesion lay proximal to L_I or was only found distal to L_{IV} dislocation was more uncommon This implies that if only the hip flexors and adductors are functioning dislocation is common but if also these muscles are paralyzed or if there is increasing function of the hip abductors the frequency of dislocation diminishes

Menelaus in 1969 was of the opinion that the deforming force was essentially due to the hip flexors with or without active adductors but he also noted that the results following transposition of the iliopsoas as abductor would have been better if at the same time more adductor tenotomies had been performed

McKibbin (1973) stated that he only performed an adductor operation if it was necessary in order to reduce a hip in myelomeningocele To achieve retention of the hip he used a splint in abduction and possibly psoas tenotomy

Carroll & Sharrard (1972) *Rueda & Carroll* (1972) and *Sharrard* (1975b) emphasized the

The extreme shows us
the way to the norm

Hypothesis

In the growing child there is a connection between the position of the head of the femur in relation to the acetabulum and the function of the surrounding muscles In particular it is the balance between the adductors and the abductors of the hip that is of significance for the stability of the hip in the frontal plane

hips in the infant takes place too early after birth for which reason he advised against the prone position for infants and suggested instead that stimulation should be given to maintain flexion at the hip

Contrary to these proposals the work of *Michelsson & Langenskiold* (1972) carries conviction They showed that in one to five weeks old rabbits the hips dislocated if the knee joint was immobilized in extension for several weeks While so immobilized the animals maintained the corresponding hip in a flexed position If the hamstring muscles (Mm ischiocruralis) had been transected prior to the above neither dislocation nor dysplasia developed They drew an analogy with prenatal infants in the breech presentation where the hips can be flexed while the knees are extended and considered that in these cases the hamstrings could be the cause of dislocation of the hips *Fettweis* (1975) made a corresponding claim that of all the various delivery presentations only those children born in a frank breech presentation had a risk of hip dislocation as high as nine times that found in the other presentations since in the breech presentation the hamstrings exert pressure on the most posterior upper part of the acetabulum

Cardinet et al (1974) mentioned several studies which had pointed out the effect of pectineus tenotomy in dysplasia in dogs However they themselves found no unambiguous effect on extirpation of m pectineus possibly because the other adductors remained untreated

Electromyelographic and light microscopic studies by *Tonnis* (1969) showed no signs of disease of muscles or nerves in congenital dislocation of the hips Some minimal changes were interpreted as a sequela of inactivity *Matsoukas et al* (1969) on the other hand found that degenerative lesions were present in all cases of muscle biopsy from 67 children with dislocation of the hip the lesions being most pronounced in the younger children *Wolff & Tonnis* (1970) by electron microscopy of the muscles around the hip joint were unable to find any changes that could explain a muscular imbalance or the contractures in the adductors in congenital dislocation

It must be concluded from these studies that we are still unable to decide which muscles are of the greatest significance for the development of dislocation of the hip It is only when a knee is held artificially extended while simultaneously the hip is in flexion that we now know that the hamstrings are the deforming force With a valgus hip the hip abductors will function with reduced force and this in turn may result in a further valgus position

The »cerebral palsy« hip

Silfverskjold s study from 1924 and *Scheibel s* study from 1928 provide historical reviews of earlier treatment of the sequelae of cerebral palsy (*Little s disease*)

In 1836 Strohmeyer carried out a tenotomy on the tendo Achilles in the subsequent orthopaedic surgeon *J W Little* However it was not until 1880 that reports were published on the treatment of contractures at the hip when *Sayre Jr* reported at the Annual Meeting of the American Orthopedic Association that his father had treated adduction contractures for many years solely by clitorectomy and circumcision! In 1897 the same deformity was treated by *Lorenz* by means of obturator neurectomy

In 1902 *Ludloff* described a case of bilateral dislocation of the hip in a 6 year old girl with spastic paresis He pointed out that the acetabulum was less deformed than in congenital dislocation The hips could not be reduced and in his opinion the reason for the dislocation was spasticity in the adductors and flexors

In 1906 *Gaugele* proposed transection of the adductors and flexors but he was unable to reduce his three cases of dislocation He quoted a figure of 40 per cent for the incidence of

significance of starting with extensive adductor release before any possible further intervention at the hip

London & Nichols (1975) reported that results were improved if transposition of the adductors was carried out before an operation upon the iliopsoas

Observations such as the above show that dislocation may develop in association with muscular imbalance around the hip joint

Opinions are divided however on whether it is imbalance between abductors and adductors or between flexors and extensors that has the greater significance

Experimental hip preparations

The literature does not seem to include any experimental studies on animals which might solve the problem raised above

Brooks & Wardle (1962) showed in experiments on 10 decalcified femora and hip joints that when the soft bones were exposed to load via the muscle preparations the psoas muscle deformed the neck of the femur into valgus position and the adductor magnus produced a varus position However they did not seem to take into account that the child is a growing individual and that the deforming effect on the epiphysis of the femur may release growth potentials which exert contrary effects

Bragard reached the same result in 1925 as a result of experiments with an apparatus in which the femur and hip were set up and a cordpull demonstrated the effect of the muscles on bones and joint He also found that theoretically the adductors should have a varus effect on the neck of the femur but accepted that in practice the adductors had a valgus effect in growing children

On the basis of experiments with a hip joint model consisting of a pelvis preparation with hip joint and femur in which the major muscle groups were replaced by chains with strain gauges *Merchant* (1965) found that the requirement for optimum functioning of the abductors is a stable mobile and painless hip The force of the abductors should be adequate and the length of the »lever« should be sufficiently long The femoral »lever« is the distance from the trochanter major to the axis for abduction and adduction running through the head of the femur the distance being measured at right angles to the direction of pull of the hip abductors (see Fig 13 p 61)

A *valgus deformity of the neck of the femur is taken to signify that the angle between the* body and neck of the femur is pathologically increased The angle may be determined on an antero posterior radiograph of the hip during maximum internal rotation so that any increased anteversion is abolished *Inman* (1947) put forward the theory that coxa valga is due to subjects with paresis of the abductors putting an increased load over the hip As a consequence the resultant of the forces acting on the head of the femur becomes more vertical and as the epiphyseal disc is at right angles to the forces acting on it the epiphysis becomes more horizontal with the result that a valgus hip develops In contrast to this theory *Rang* (1969) showed how a reduced effect of the abductors could be considered to result in reduced osteogenesis at the epiphysis of the trochanter major because of the diminished stimulation by the muscles so that the valgus position is due to the absence of new bone

From experiments on rats *Sijbrandij* (1965) showed that the hip joint became dislocated if the hips were immobilized in the extended position and concluded that the extension of the hip after birth is of significance for the pathogenesis of dislocation The dislocating effect of the extension may be due to the iliopsoas as has also been suggested by *O Malley* (1965) and *Glauber et al* (1967) but in Sijbrandij s experiment the hips appear to have been adducted at the same time so it could also be that the absence of abduction was responsible for the deformity Among others *Fettweis* (1971) reported that extension of the

duction encouraging dislocation of the hip

Baker et al in 1962 wrote that »every cerebral palsy patient should be considered until proved otherwise to have a hip problem and have early and repeated roentgenographic examination« They recommended adductor and gracilis tenotomy with resection of the external obturator nerve as well as distal elongation of the hamstrings to retain the hip in position

Lamb & Pollock in 1962 considered that subluxation is due to weak abductors and extensors giving a tendency to coxa valga and that it is necessary to provide early treatment before an irreversible deformity has developed

A detailed bibliography was available in *Acta Orthopædica Belgica* (29 485 505) already in 1963 with 625 references to studies on cerebral palsy supplemented in 1967 by a further 90 references in *Revue de Chirurgie Orthopedique* (53 787 790)

Lewis et al in 1964 stated that in cerebral palsy abnormal muscular force influences the shape of the proximal part of the femur

Hagberg et al in 1961 analyzed a large material of 41 patients who had undergone intrapelvic obturator neurectomy for spasticity but unfortunately they did not report whether there were any effects on the hip joint

Samilson et al in 1967 analyzed a material of 105 children with cerebral palsy and low intelligence One conclusion was that after the age of 12 years a dislocated hip cannot be reduced by means of adductor tenotomy alone but femur osteotomy must be employed in addition

Smith in 1969 did not consider that the hip flexors play any major role in dislocation of the hip

Barry in 1969 considered the etiology of spastic dislocation as possibly due to an imbalance between the muscles around the hip joint especially between the abductors and adductors but he also considered that m gracilis and the hamstrings can be the main cause of the condition

Samilson [redacted] *al* in 1972 studied a material of 274 spastic patients with hip problems The dislocation of the hip was found to be due to retained neonatal reflexes muscular imbalance and contractures coxa valga with anteversion and a high acetabular angle

Fujiwara & Basmajian in 1974 also considered that »stigmata of neurological immaturity« may play a part in the dislocation of the hip They found in electromyographic studies that adductor activity in association with an underlying flexor activity is a possible dislocating factor

Feldkamp & Katthagen in 1975 showed that the stability of the hip is improved by lengthening the hamstrings However these operations were often combined simultaneously with adductor operations

Finns in 1975 stated that the cause of subluxation and dislocation in cerebral palsy must involve the hamstrings together with the gracilis and the other adductors

Sharrard et al in 1975 analyzed a treated and an untreated series of children with cerebral palsy All the children had reduced abduction and deformity at the hip as shown by radiography One of the conclusions reached was that normal hip abduction is possibly not the most significant factor when the aim is to achieve stability of the hip but that balance between abductors and adductors and between flexors and extensors is more suited to a maintenance of hip stability

Just as with the hip in myelomeningocele and in experimental preparations a review of the literature on the »cerebral palsy« hip has also been unable to decide the correctness of the hypothesis presented at the beginning of this study

All authors are of the opinion that experience and in a relatively few studies where objec

dislocation in cases of Little's disease *Wollenberg* in 1908 reported that the dislocations were produced by spasm in the adductors, and *Weber* in 1911 found 4 cases of dislocation among 30 children with spastic palsy

Kunne in 1914 reviewed the histories of 23 diplegics, 17 of whom had dislocation of the hips, and he reported that paralysis of the hip abductors and external rotators produces »luxatio iliaca«, and that paralysis of the adductors gives »luxatio infrapubica« As did *Feldkamp* later in 1976, *Kunne* described the asymmetrical abnormal position which develops when the child prefers to lie always on the same side, so that the hip which is placed uppermost is adducted and may dislocate *Samilson et al* in 1972 described the condition as »the wind blown hip«, and *Fulford & Brown* (1976) called it »the windswept child«

Lange in 1921, on theoretical considerations, concluded that the adductors must be the cause of coxa valga in spastic palsy

Watson Jones in 1926 was the first writer in the Anglo Saxon literature to present a case of »the very rare« combination of cerebral palsy and dislocation of the hip He argued that the primary cause was muscular imbalance with contracture in the adductors and, of less significance, also in the hip flexors As a result of resection of the n obturatorius and flexor tenotomy (without involving the psoas tendon), together with an abduction splint for 6 months, his patient's hips became stabilized and the general condition improved

Klopfer in 1950 considered that in spastic diplegia the bones and in particular the acetabulum are the site of an incomplete development (»status hypoplasticus«), and that in some cases this leads to dislocation In other cases the dislocation is due to a muscular imbalance

Mathews et al in 1953 claimed that dislocation of the hip had not been described previously in connection with cerebral palsy, and proposed adductor operation with anterior n obturatorius resection as treatment

Mau in 1954 found that a valgus position was due to preponderance of adductors in relation to abductors, and recommended splinting in the abducted position He attempted to reduce dislocated hips in two cases without any improvement, as both patients had considerable adduction contractures following treatment

Keats in 1957 recommended combined adductor and gracilis tenotomy with selective n obturatorius resection in correction of the adduction contractures

Pollock & Sharrard in 1958 found that in dislocation and subluxation adduction contractures were always present but only half of the cases showed contractures of the flexors in addition At that time subluxations were not treated if it was felt that the child would not acquire any ability to ambulate

Phelps in 1959 considered that the cause of dislocation is coxa valga and contractures or spasticity in the adductors and gracilis Since a greater proportion of cases with coxa valga were found among spastic children whose legs were not exposed to weight bearing than among spastic children who could ambulate, it was concluded that valgus develops as a result of absence of weight bearing by the legs

Le Cœur et al in 1959 claimed that dislocation is favoured by young age paralysis of the abductors and retention of abductor function in the opposite hip but that dislocation is provoked by the hamstrings

Banks & Green in 1960 recommended early operation and considered that operation on the adductors is to some extent preventive, but is also useful in dislocation which is already present They combined treatment with obturator neurectomy

Plum in 1961 recommended resection of the n obturatorius for adduction contracture but without mentioning the possible effect on the hip

Jones in 1962 found that adduction increases the effective valgus position of the hip and recommended early varus osteotomy, even in patients who would never be able to walk

Michele in 1962 considered that the iliopsoas produces an external rotation flexion ad

and after the operations (Migration Index) the Mann Whitney signed rank test was used A parametric test was used in determining correlation coefficients

As a rule collected data are quoted with a »mean« In the author s opinion this should only be done when the data are uniformly distributed But when the data are scanty and the »range« between greatest and smallest value is large the individual datum which deviates considerably from the mean will thus have too great a significance in deciding this In all cases therefore the »median« has been used instead (the mid value) corresponding to the 50 percentile

Age and time of observation are given in years

tive criteria are used the results demonstrate a relation between the stability of the hip and the function of the surrounding muscles Most are of the opinion that the factor leading to dislocation is imbalance between the better functioning and possibly contracted adductors *including the m gracilis and the flexors* Some few investigators claim that the hamstrings in their experience have a deforming effect

Review of the present investigation

In order to establish the hypothesis presented animal experiments could be carried out to produce muscular imbalance at the hip so as to analyze the dislocating effect of various muscle groups Alternatively it should be possible in children with cerebral palsy to provide treatment for corresponding imbalance between muscles and measure the results of treatment on the hip joint by radiographic studies

Children may belong to the animal kingdom but not to the group in which experiments are permissible Operations have therefore not been performed with a view to furthering the *investigation* and the study has been restricted to a purely prospective recording of patients and surgical intervention since 1969 Apart from some few cases in the follow up of the results of operations on the hamstrings radiographic investigations have not been made with a direct view to *the present study Such limitations have reduced the scope of the material* very considerably

During the course of the work it was found necessary to solve several problems before the actual analysis of the muscle surgery could be done The result of the study has thus involved more than merely returning a »yes« or »no« to the hypothesis

First the measuring method had to be selected on the basis of the literature and the author s own investigations of the significance of rotation of the hip for the radiological picture of the stability of the hip Next it appeared that there was some uncertainty as to how an optimal hip joint in childhood appears on the radiograph It was therefore necessary to produce a series of »normal« hip joints and compare the results from this with those from the *measuring method most commonly employed previously Following this it was possible to* establish definitions for the various degrees of hip deformation

In order to demonstrate whether there was any possible effect of muscle surgery on the stability of the hip it was first necessary to examine whether the untreated »cerebral palsy« hip undergoes a spontaneous lateral migration in relation to the acetabulum Next it was necessary to examine whether in fact any effect was actually achieved by soft tissue surgery and once this had been confirmed determine the magnitude of the result after one or more operations

Since adductor intervention is often combined with other soft tissue surgery other consecutive series had to be collected for the more uncommon isolated soft tissue operations and the results analyzed *before this analysis could be made for the adductor operations*

Finally a decision could be made on the question does contracture in the adductors have any significance as a deforming factor for the hip?

Treatment of data

The statistical analysis was carried out on the screen programmes of the Rigshospital

Non parametric tests were used to analyze *the results In those cases were the stability* (Migration Percentage) of the same hip could be measured before and after treatment the Wilcoxon test for paired differences was employed When it was a question of comparing *non paired values* as in measurements of the rate with which different hips migrated before

and after the operations (Migration Index) the Mann Whitney signed rank test was used A parametric test was used in determining correlation coefficients

As a rule collected data are quoted with a »mean« In the author s opinion this should only be done when the data are uniformly distributed But when the data are scanty and the »range« between greatest and smallest value is large the individual datum which deviates considerably from the mean will thus have too great a significance in deciding this In all cases therefore the »median« has been used instead (the mid value) corresponding to the 50 percentile

Age and time of observation are given in years^{months}

Chapter II

Measuring method

On a standard radiograph the method should provide a reproducible measurement for the position of the femoral head in the acetabulum, without the measurement being affected by pelvic inclination (kyphosis lordosis) In addition, the measurement should be possible by means of a simple measuring instrument

Methods

Hilgenreiner in 1925 introduced the *acetabular angle* (Fig 1) This angle is measured be tween the *Y line* (*Hilgenreiner's line*) and a line from the Y cartilage to the edge of the ace tabulum The measurement is synonymous with the *acetabular index*, introduced by *Klein berg & Liebermann* in 1936 This is a frequently employed index, and »normal series« are available for age groups also beyond childhood (*Severin* 1941, *Massie & Howorth* 1950, *Caf fey et al* 1956, *Harris et al* 1960, *Baker et al* 1962, and *Lusted & Keats* 1967)

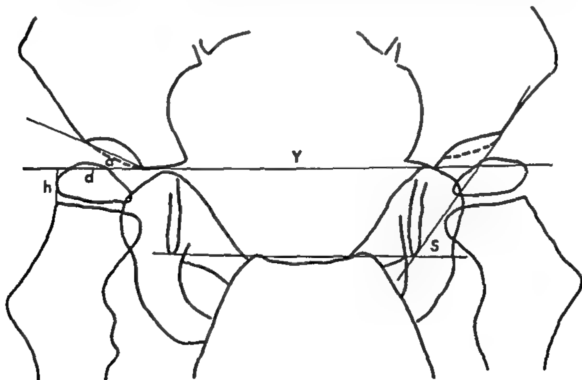

Figure 1
Right hip Hilgenreiner s three measurements in relation to the Y line a) The acetabular angle h) The least distance from the femoral diaphysis to the Y line d) Distance from the h line to the Y shaped cartilage
Left hip Sharp s acetabular angle marked S In contrast to Hilgenreiner s angle this angle is drawn in relation to the U figure

Ball & Kommenda (1968) and *Janotec* (1973) showed that the angle varies with the inclina tion of the pelvis The angle being greatest in kyphosis and smallest in lordosis for example as a result of hip flexion contracture which limits the applicability of the method *Lauren son* (1959) has provided a critical review of these topics

Sharp (1961) described another acetabular angle drawn between the distal tip of the U figure (pelvic tear drop) and the lateral edge of the acetabular roof This angle likewise provides an expression for the development of the acetabulum

Andren & Rosen (1958) claimed that hypoplasia of the acetabulum is the result and not the cause of congenital dislocation In experimental studies *Langenskiold et al* (1962) *Smith et al* (1963) *Bohr et al* (1965) and *Sijbrandy* (1965) have shown that the acetabulum be comes hypoplastic as a consequence of dislocation of the femoral head In corresponding studies *Harris et al* (1975) showed that the acetabulum can become remodelled if reduc tion of the head is complete in children up to the age of four years It would therefore ap pear more logical to measure the position of the head in the acetabulum instead of measur ing the outcome of a suboptimal acetabular relation in the form of a hypoplasia of the ace tabulum

Already in 1925 *Hilgenreiner* pointed out that the most important sign of a threatening dis location is a separation of the femoral head from the acetabulum and that this can be de cided before the head is visible on an X ray The proximal displacement of the femoral head is measured by the *h distance* from the diaphysis of the femur to the Y line and the lateral displacement by the *d distance* from the femoral diaphysis to the acetabulum (Fig 1)

As there is a visible femoral head epiphysis already at the age of 7 months in 90 per cent of the hip joints (*Harris et al*; 1960) there is no reason for using the above indirect method in the present study

Kemp & Boldero (1966) proposed as an expression for lateral displacement in Calve Legg Perthes disease the ratio of the least horizontal distance from the femoral head to the ace tabulum on the affected side to the corresponding distance on the healthy side This index can therefore only be used in unilateral changes

Shenton s line is an arc drawn on the radiograph from the lesser trochanter along the medial inferior surface of the femoral neck and joins the superior medial border of the obturator foramen Normally this is a regular smooth arc congrous on both sides (*Martin* [illegible] A broken line expresses the [illegible] example in *Trevor et al* [illegible] (1941) regarded Shenton s [illegible] for static changes in the hip *Sharrard et al* (1975) stated that a break in the line indicates dysplasia

In contrad [illegible] tally [illegible] and th [illegible] s excludes the possibility of using the method in children with hip flexion contracture for example

In 1939 *Wiberg* proposed the *CE angle* (CE = Centre Edge) measured between a line through the centre of the femoral head at right angles to the connecting line through the centres of both femoral heads and a line through the centre of the femoral head to the ace tabular edge The method was developed to apply to adults with the limitation that the CE angle is not suitable for any other pathological cases than the ones bordering on the normal.

Chapter II

Measuring method

On a standard radiograph, the method should provide a reproducible measurement for the position of the femoral head in the acetabulum, without the measurement being affected by pelvic inclination (kyphosis lordosis). In addition, the measurement should be possible by means of a simple measuring instrument.

Methods

Hilgenreiner in 1925 introduced the *acetabular angle* (Fig. 1). This angle is measured between the *Y line* (*Hilgenreiner's line*) and a line from the Y cartilage to the edge of the acetabulum. The measurement is synonymous with the *acetabular index*, introduced by *Kleinberg & Liebermann* in 1936. This is a frequently employed index, and »normal series« are available for age groups also beyond childhood (*Severin* 1941, *Massie & Howorth* 1950, *Caffey et al.* 1956, *Harris et al.* 1960, *Baker et al.* 1962, and *Lusted & Keats* 1967).

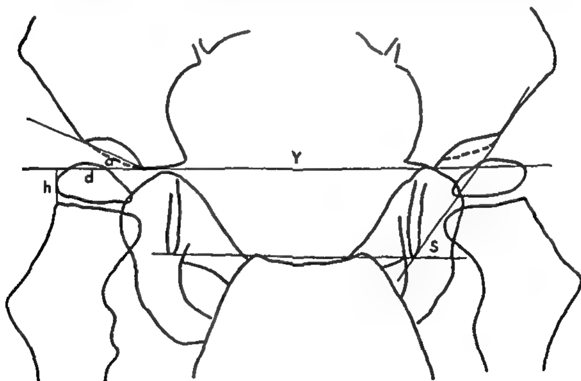

Figure 1
Right hip. Hilgenreiner's three measurements in relation to the Y line. a) The acetabular angle. h) The least distance from the femoral diaphysis to the Y line. d) Distance from the h line to the Y shaped cartilage.
Left hip. Sharp's acetabular angle marked S. In contrast to Hilgenreiner's angle this angle is drawn in relation to the U figure.

the original one *Trevor et al* (1975) refer to *MacKenzie* and therefore presumably also use the modified angle This is probably also the case with the majority of recent authors employing this method

Another error of interpretation is found in the determination of the centre of the femoral head (*Sharp* 1961) In determining this centre a transparent ruler is used inscribed with concentric circles In adults and older children one of these circles is made to cover the head thus giving the centre At the same time one of the larger circles will be found to follow the acetabular curve In younger children or in cases of subluxation where the femoral head is often not circular the centre of the acetabular curve is used in practice a point which in younger children lies within the femoral diaphysis (*Massie & Howorth* 1950 *Wiberg* 1975)

A difficulty in determining the CE angle is that the edge of the acetabulum may be difficult to define particularly when there is lateral displacement of the femoral head where the border which is normally well marked is rounded and obtusely angled (*Ludloff* 1902 *Weber* 1911 *Putti* 1937 *Martin* 1951 *Hart* 1952 and *Bjerkreim* 1974a)

Heyman & Herndon (1950) and *Snyder* (1975) for example used the most lateral border of the acetabulum whereas *Harris et al* (1975) used the medial border when two boundaries were visible This implies that »the lateral border of the acetabulum may be the subject of considerable subjective assessment« (*Medbo* 1961)

Massie & Howorth (1950) stated that the CE angle is independent of abduction adduction or rotation of the femur since the centre will be the point around which the movement takes place so long as the femoral head is circular But the femoral head cannot be presupposed circular since it is the pathological hip joints whose evaluation we are interested in *Sharrard* (1969) pointed out that the centre for the movement of abduction adduction moves distally in the femoral diaphysis on subluxation of the head of the femur This was also pointed out by *Reimers* (1971 and 1973a) This means that on adduction of the femur a smaller part of the femoral head becomes covered by the acetabulum and as shown in Fig 3 abduction results in a larger part of the head being covered whereby the CE angle at the same time becomes larger

Figure 3
The same hip joint has been radiographed (a p view) in a) maximum internal rotation b) neutral rotation c) abduction

In abduction the femoral head migrates inwards in relation to Perkins line marked as a vertical line from the acetabular rim

Severin (1941) showed that *Wiberg's* normal series, where a CE angle of more than 25° was found to be normal, could be used down to the age of 18 years. Severin added another normal material, and found that a CE angle of at least 20° was normal for children between 6 years and 14 years.

Massie & Howorth modified the method in 1950, so that the line through the centres was replaced by a line which is horizontal in relation to the pelvis, as shown in Fig. 2. They presented a normal material down to an age of 1 month, but stated that the method was uncertain under the age of 3 years because the epiphysis of the femoral head might ossify irregularly (*Putti* 1937). They showed that a CE angle of at least 20° was normal from the age of 3 years and upwards.

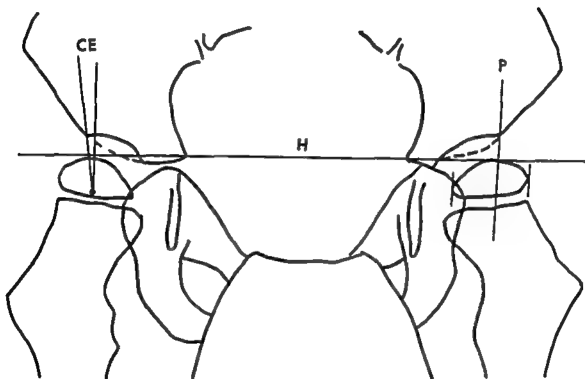

Figure 2
Right hip. The modified CE angle, where the vertical line is perpendicular to a line H which is horizontal in relation to the pelvis, in distinction to the true CE angle, where the vertical line is at right angles to a line joining the centres of the femoral head.
Left hip. P corresponds to Perkins' line, perpendicular to the horizontal line and passing through the acetabular edge.

Lude & Taillard (1964) found a modified CE angle of 12° as a mean value by radiography of »normal« infant hips between the ages of 3 months and 2 years.

Sharp (1961) pointed out that since the axis of the original CE angle has to go through the centres of both femoral heads, false values are obtained when the contralateral hip is subluxated.

Lequesne (1963) proposed the *VCE angle*, where V indicates that the perpendicular line from the centre of the femoral head is vertical in relation to the pelvis, corresponding to *Massie & Howard's* modification of the CE angle.

Ravelli (1953), *Esteve* (1960) and *Fredensborg* (1975) all use the original angle. *Medbo* (1965) and *Snyder* (1975) possibly use the same definition for the angle. *Muller* (1956) and *MacKenzie et al.* (1960) use the modified definition and are under the impression that it is

the original one *Trevor et al* (1975) refer to *MacKenzie* and therefore presumably also use the modified angle This is probably also the case with the majority of recent authors employing this method

Another error of interpretation is found in the determination of the centre of the femoral head (*Sharp* 1961) In determining this centre, a transparent ruler is used inscribed with concentric circles In adults and older children one of these circles is made to cover the head thus giving the centre At the same time one of the larger circles will be found to follow the acetabular curve In younger children or in cases of subluxation where the femoral head is often not circular the centre of the acetabular curve is used in practice, a point which in younger children lies within the femoral diaphysis (*Massie & Howorth* 1950 *Wiberg* 1975)

A difficulty in determining the CE angle is that the edge of the acetabulum may be difficult to define particularly when there is lateral displacement of the femoral head where the border which is normally well marked is rounded and obtusely angled (*Ludloff* 1902 *Weber* 1911 *Putti* 1937, *Martin* 1951, *Hart* 1952 and *Bjerkreim* 1974a)

Heyman & Herndon (1950) and *Snyder* (1975) for example used the most lateral border of the acetabulum whereas *Harris et al* (1975) used the medial border when two boundaries were visible This implies that »the lateral border of the acetabulum may be the subject of considerable subjective assessment« (*Medbö* 1961)

Massie & Howorth (1950) stated that the CE angle is independent of abduction adduction or rotation of the femur since the centre will be the point around which the movement takes place so long as the femoral head is circular But the femoral head cannot be presupposed circular since it is the pathological hip joints whose evaluation we are interested in *Sharrard* (1969) pointed out that the centre for the movement of abduction adduction moves distally in the femoral diaphysis on subluxation of the head of the femur This was also pointed out by *Reimers* (1971 and 1973a) This means that on adduction of the femur a smaller part of the femoral head becomes covered by the acetabulum and as shown in Fig 3 abduction results in a larger part of the head being covered whereby the CE angle at the same time becomes larger

Figure 3
The same hip joint has been radiographed (a p view) in a) maximum internal rotation b) neutral rotation c) abduction

In abduction the femoral head migrates inwards in relation to Perkins line marked as a vertical line from the acetabular rim

Severin (1941) showed that *Wiberg's normal series* where a CE angle of more than 25° was found to be *normal* could be used down to the age of 18 years Severin added another normal material and found that a CE angle of at least 20° was normal for children between 6 years and 14 years

Massie & Howorth modified the method in 1950 *so that the line through the centres* was replaced by a line which is horizontal in relation to the pelvis as shown in Fig 2 They presented a *normal material* down to an age of 1 month but stated *that the method* was uncertain under the age of 3 years because the epiphysis of the femoral head might ossify irregularly (*Putti* 1937) They showed that a CE angle of at least 20° was normal from the age of 3 years and upwards

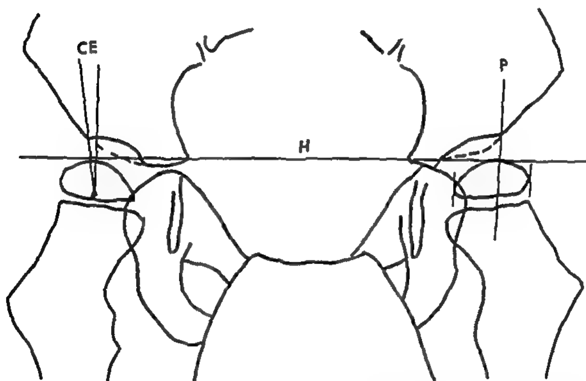

Figure 2

CE angle where the vertical line is at right

to the horizontal line and passing through the

acetabular edge

Lude & Taillard (1964) found a modified CE angle of 12° as a mean value by radiography of »normal« infant hips between the ages of 3 months and 2 years

Sharp (1961) pointed out that since the axis of the original CE angle has to go through the centres of both femoral heads false values are obtained when the contralateral hip is subluxated

Lequesne (1963) proposed the *V CE angle* where V indicates that the perpendicular line from the centre of the femoral head is vertical in *relation to the pelvis corresponding* to *Massie & Howard's* modification of the CE angle

Ravelli (1953) *Esteve* (1960) and *Fredensborg* (1975) all use the original angle *Medbo* (1965) and *Snyder* (1975) possibly use the same definition for the angle *Muller* (1956) and *MacKenzie et al* (1960) use the modified definition and are under the impression that it is

those few which have really increased our knowledge of measurements of the femoral head in relation to the acetabulum

The acetabular angle (acetabular index) does not provide a direct measure of the placing of the femoral head in the acetabulum The CE angle and Perkins line on the contrary do provide this but in addition to the difficulty of an unambiguous definition of the acetabular border there is also the difficulty in the case of the CE angle of determining the centre of the femoral head

In describing the status of the hip therefore I have in the present study used Perkins line which runs from the lateral edge of the roof of the acetabulum We can then measure in the horizontal plane the part of the femoral head extending beyond the line and express this as a percentage of the entire width of the visible part of the femoral head likewise measured in the horizontal plane

A transparent ruler can be used for the measurement with a mm scale and with engraved transverse lines as shown in Fig 4

Figure 4
Measuring the migration percentage by means of a transparent ruler with transverse lines

By the use of this measuring instrument a measuring *error of* ± 0 5 mm is found for the smallest femoral heads measuring [illegible] mm corresponding *to an uncertainty* of at most ± 10% *In larger children* where more of the femoral head [illegible] visible on a radiograph th[illegible] actual uncertainty becomes less but *as the position* of the acetabular edge may be difficult to define without ambiguity here too *we must reckon* with an uncertainty *of* ± 10%

In order to emphasize the dynamic *element in* the placing of the articular head the term »Migration Percentage« (MP) is used *from an idea* suggested by *Mercer Rang* (1975) indicating how large a part of the femoral head *has migrated* [illegible]

As early as [illegible]
relation of the [illegible]
used the expres[illegible]

Perkins in 1928 described the line which bears his name The line was drawn from th prominent outer lower angle of the ilium (»anterior inferior spine«) at right angles to a h zontal line drawn between the innermost parts of the ilium at the Y shaped cartilage of acetabulum The placing of the femoral head can then be evaluated from these two lines shown in Fig 2

Perkins line is the same line as in *Putti s system* fra 1932 and *Ombredanne* in described a similar vertical line which bears his name in French and German literature corresponding line the *V line* was described by *Martin* in 1951

Medbo in 1961 measured in mm the part of the femoral head which projected b Perkins line The same measurement was made by *Zweymuller & Wicke* in 1973

Heyman & Herndon in 1950 defined an Acetabulum Head Index where the portion of the femoral head covered by the acetabular roof was divided by the width of the head and this fraction multiplied by 100 *Bellyei et al* (1975) recommended the method and re garded it as the most important prognostic sign in Legg Calvé Perthes disease *Snyder* (1975) used the *percentage of subluxation* as measured by the proportion of the femoral head lying lateral to the lateral margin of the acetabulum

Schiller showed in 1972 that the advantage of measuring the relation of the head to the acetabular corner (= Perkins line) is that the measurements do not vary significantly in pel vic inclination (kyphosis lordosis) This also means that a urograph can be used with the beam centred in the mid line Schiller also showed that rotation of the pelvis around a ver tical axis for example in unilateral atrophy of the gluteal muscles does not result in sig nificant changes in the measurements

In abduction adduction *of the femora the same considerations hold as in the case* of the CE angle (see Fig 3) so that the legs must be placed in the mid position during radio graphy

Just as in determining the CE angle there may be difficulty in an objective identification of the acetabular corner when the border is rounded In the present study the acetabular *corner is defined as the lateral edge of the roof of the acetabulum*

Rubens Duval et al in 1963 gave a system for measuring the statics of the hip joint by means of three angles and the ratio between two distances *This measuring method is completely* dependent on the rotation of the hip since the angulation of the neck and the projection of the axis of the neck in the acetabulum have a decisive significance for the result This method has therefore been rejected in the present study

Zsernaviczky & Turk in 1974 stated that in the normal hip in infants the centre of the femo ral head must lie on a straight line from the acetabular corner to the medial proximal edge of the diaphysis of the femur (*the Z line*) This measurement appears to be very accurate but only remains defined up to the age of one year *so that it cannot be employed here*

Many authors describe their own systems which are combinations of the methods men tioned and others but these are without interest for the present study *Smith et al* in *1968* developed an efficient system along known lines but like *Hilgenreiner* gave the distances to *the femoral diaphyses* Several authors use point systems based in part on the measuring methods mentioned *Trevor et al* in 1975 proposed a variation of the system of *MacKenzie et al* from 1960 their system including for example the CE angle Shenton s line pain mo bility and so on and is thus of no interest here

Conclusion

This review of the literature has only included the most important studies in particular

those few which have really increased our knowledge of measurements of the femoral head in relation to the acetabulum

The acetabular angle (acetabular index) does not provide a direct measure of the placing of the femoral head in the acetabulum The CE angle and Perkins' line, on the contrary, do provide this but in addition to the difficulty of an unambiguous definition of the acetabular border, there is also the difficulty in the case of the CE angle of determining the centre of the femoral head

In describing the status of the hip, therefore, I have in the present study used Perkins' line, which runs from the lateral edge of the roof of the acetabulum We can then measure, in the horizontal plane the part of the femoral head extending beyond the line, and express this as a percentage of the entire width of the visible part of the femoral head likewise measured in the horizontal plane

A transparent ruler can be used for the measurement, with a mm scale and with engraved transverse lines, as shown in Fig 4

Figure 4
Measuring the *migration percentage* by means of a transparent ruler with transverse lines

By the use of this measuring instrument, a measuring error of ± 0 5 mm is found for the smallest femoral heads measuring 5 mm, corresponding to an uncertainty of at most ± 10% In larger children where more of the femoral head is visible on a radiograph, the actual uncertainty becomes less but as the position of the acetabular edge may be difficult to define without ambiguity, here too we must reckon with an uncertainty of ± 10%

In order to emphasize the dynamic element in the placing of the articular head the term »Migration Percentage« (*MP*) is used from an idea suggested by *Mercer Rang (1975)*, indicating how large a part of the femoral head has migrated external to Perkins' line

As early as 1928 *Mezzari* used the expression »la migrazione« to designate the variable relation of the femoral head to the acetabulum In the English literature, *Mathews et al* used the expression in 1953

We know that the MP varies according to the degree of abduction adduction of the but we do not know what significance the rotation has for the measurements This examined therefore before it is possible to establish a standard for positioning the c radiography

The significance of the hip rotation for the migration percentage

A priori one would not expect internal or external rotation of the femur to influe relation of the femoral head to the acetabulum on a radiograph If it did so it woul that the femoral head migrates inwards or outwards in the acetabulum for exampl the hips rotate during walking

It is often reported that the hips have been positioned in »mean« rotation By this i that after having measured the maximum rotational mobility of the hip in simult extension the leg has been positioned and immobilized midway between maximum i and maximum external rotation This is presumably so as to ignore variations in the of anteversion If this procedure was to be carried out exactly it would be time cons so that it must be considered that by »mean« rotation has been meant »neutral« ro with patella pointing directly forward

Sharrard et al (1975) pointed out that they employed a position with the hips in »n *rotation and this is probably also the case with those authors who have not mention* position adopted or have employed »standard« rotation *Fredensborg* (1975) measur angles used the radiographs of the hips in children made by Dr Andren these film taken under maximum internal rotation

A review of the literature suggests that the significance of rotation for the relat femoral head and acetabulum has not been investigated It was therefore found neces examine this problem by measuring the MP in the same hip joint both during max internal rotation and in neutral rotation

Author's investigation

Previously it was the usual procedure to carry out a radiological examination of th joint in children in three projections maximum internal rotation neutral rotation *Lauenstein s projection* also when it was only a question of evaluating the position of t moral head in the acetabulum It was therefore possible among the examinations of dren with cerebral palsy to find a sufficient number of older radiographs of the h

Table 1 Relation between migration percentage and hip rotation

n = 67	AGE years	MIGRATION PERCENTAGE per cent		▪	P
		NEUTRAL ROTATION	INTERNAL ROTATION		
median	4^{3}	19	15	0 88	< 0 0
range	1^{3} 14^{8}	0 38	0 43		

which the femoral head reached or passed Perkins line In all cases the rotation has been in dicated on the film The individual measurements are seen in the table of raw data on p 78

Table 1 shows the result of the analysis There is a difference between the MP of 19 per cent in neutral rotation and the MP of 15 per cent in maximum internal rotation but the correlation coefficient r = 0 88 suggests a good relationship and the actual numerical dif ference is not particularly great

Discussion

As it was not considered justifiable to take radiographs as an aid to this study, it is not cer tain that the films employed here have been taken precisely with the desired hip rotations On the other hand, these are films made according to standard procedures so that the analysis may nevertheless be employed clinically

As mentioned it was not anticipated that a difference in MP would be found associated with different states of rotation of the hip One explanation for the difference found is that simultaneously with rotating the hip internally, the patient lying in the supine position, there is a tendency to abduct the hip a few degrees As a result, the femoral head becomes more covered by the acetabulum so that the MP decreases

When a child with asymmetrical contractures of the musculature around the hip joints is allowed to take up a spontaneous position when lying supine i e when the child is allowed to place the legs as preferred a radiograph of the hip joints gives a more functional impres sion of the relation between the femoral head and the acetabulum However since the posi tioning of the head can vary from time to time, the spontaneous position cannot be used as a standard method but only as a stage in a special investigation

Conclusion

The difference in the MP between the positions internal and neutral rotation, is so small that in a radiological investigation of the MP of the hip the difference does not discriminate between the use of these positions

Radiological investigation of the stability of the hip joint

After th [illegible]
that in a [illegible]
sible pa [illegible] to the acetabulum in the frontal plane, the posi tion of choice is with the child supine with the hip in the neutral position This is ensured by holding the knees together at the same level with the patellae pointing forward The beam of radiation should be centred vertically in the mid line of the body

Urography and colonic investigations can be used if the film shows that the femora and the hip joints are in the neutral abduction adduction position

The measurement used is the MP which indicates how large a part of the femoral head extends beyond Perkins line in proportion to the width of the entire head

We know that the MP varies according to the degree of abduction adduction of the femur but we do not know what significance the rotation has for the measurements This must be examined therefore before it is possible to establish a standard for positioning the child for radiography

The significance of the hip rotation for the migration percentage

A priori one would not expect internal or external rotation of the femur to influence the relation of the femoral head to the acetabulum on a radiograph If it did so it would imply that the femoral head migrates inwards or outwards in the acetabulum for example when the hips rotate during walking

It is often reported that the hips have been positioned in »mean« rotation By this is meant that after having measured the maximum rotational mobility of the hip in simultaneous extension the leg has been positioned and immobilized midway between maximum internal and maximum external rotation This is presumably so as to ignore variations in the degree of anteversion If this procedure was to be carried out exactly it would be time consuming so that it must be considered that by »mean« rotation has been meant »neutral« rotation with patella pointing directly forward

Sharrard et al (1975) pointed out that they employed a position with the hips in »neutral« rotation and this is probably also the case with those authors who have not mentioned the position adopted or have employed »standard« rotation *Fredensborg* (1975) measuring CE angles used the radiographs of the hips in children made by Dr Andrén these films were taken under maximum internal rotation

A review of the literature suggests that the significance of rotation for the relation of femoral head and acetabulum has not been investigated It was therefore found necessary to examine this problem by measuring the MP in the same hip joint both during maximum internal rotation and in neutral rotation

Author's investigation

Previously it was the usual procedure to carry out a radiological examination of the hip joint in children in three projections maximum internal rotation neutral rotation and Lauenstein s projection also when it was only a question of evaluating the position of the femoral head in the acetabulum It was therefore possible among the examinations of children with cerebral palsy to find a sufficient number of older radiographs of the hip in

Table 1 Relation between migration percentage and hip rotation

n = 67	AGE years	MIGRATION PERCENTAGE per cent		r	P
		NEUTRAL ROTATION	INTERNAL ROTATION		
median	4^3	19	15	0 88	< 0 001
range	1^3 14^8	0 38	0 43		

Table 2 Relation between CE angle and corresponding migration percentage

n = 123	AGE years	CE ANGLE degrees	MIGRATION PERCENTAGE per cent	r	P
median	5^{2}	17	18	−0 76	< 0 001
range	1^{10} 14^{8}	38 0	0 47		

Table 2 summarizes the results and shows that there is a negative correlation between the CE angle and the MP with r = −0 76 where r is significantly different from 0 as P < 0 001

Conclusion

The investigation supports Snyder s analysis As the correlation does not permit normal values of CE angles to be converted to MP measurements it is therefore necessary to construct a new normal material of MPs

Preparation of a »normal material«

Medbo pointed out in 1965 that no great agreement existed in the literature as to what constituted the radiological picture of a normal hip in young children and he discussed the difficulties of defining what was »normal«

A few examples of material selected *to represent normal hips will illustrate* the problems involved

Wiberg s normal material *from 1939 consisted of radio*graphs of the hip joint from 200 patients between 20 and 35 years of age without signs or symptoms of disease of the hip Wiberg pointed out however that they could develop signs or symptoms later

Sharp in 1961 defined a good hip as a joint which should last a man throughout his life time This *normal material of Sharp s consisted of 100* patients over the age of 60 years without any signs of osteoarthrosis of the hip

The *material of Busse et al in 1972* consists of randomly selected radiographs of 817 hips from persons over the age of 21 years The hip joints were presumably examined because of *symptoms originating here*

Severin s normal material from 1941 consisted of 200 hips in which a radiograph had been taken simply to be on the safe side These hips were normal »according to the accepted standards« The doubt expressed by Severin as to the justification of calling this a *normal material appears* from the uncertainty in setting up standards for normal

Massie & Howorth in 1950 used as their normal material a total of 350 hips *from children with foot complaints* but without complaints from the hip [illegible]

[illegible]
for [illegible]
ma [illegible] trauma or had *intermittent* hip pain

For ethical reasons a material of radiographs of normal hips in children cannot be presented The known series are therefore based on selected patient groups and can only tell us the state of the hip in the disease in question

Chapter III

»Normal material«

The literature was reviewed but without success for a »normal material« of children's hips measured with reference to Perkins line or to the acetabular edge

Perkins in 1928 stated that in children under the age of 4 years the femoral head rarely reached the line but he did not document this claim *Ombrédanne* in 1932 stated that the normal hip in children lay within the vertical line from the border of the acetabulum *Putti* made the same claim in 1932 and *Doberti & Manhood* confirmed this in 1968 *Martin* reported in 1951 that the femoral diaphysis lay within the V line (= Perkins line) *Hart* in 1952 stated that in the normal hip in children the visible part of the femoral head always lies within Perkins line However *Ingram & Farrar* in 1955 stated that in the normal hip at least 60 per cent of the epiphysis of the femoral head should be medial to the line

Medbo in 1961 stated that all children s hips lying medial to the line are »normal« and those hips that are 0 2 mm lateral to the line are »normal?« *Sharrard et al* in 1975 stated that the visible part of the femoral head is completely covered by the acetabulum when the hip is normal but on an accompanying radiograph reported to be of a normal hip part of the femoral head is seen external to the acetabular rim

In contrast to these reports several normal series of CE angles are available for various ages and if a total correlation existed between the CE angle and the MP for the same hip then one of these series of observations could be used for conversion to MPs

Relation between CE angle and migration percentage

Snyder in 1975 found that the correlation between the percentage of subluxation (= MP) and CE angle was negative with r = 0 77 As the details in the analysis are not provided and as the investigation does not appear to have been repeated by other investigators it has been found necessary to do so before possibly rejecting the use of a normal material of CE angles

Author's investigation

In order to find a satisfactory number of pathological hip joints a search was made for material among children with cerebral palsy Among these radiographs of 123 hips have been selected where the femoral head has either reached Perkins line or has migrated beyond this line

The CE angle was measured by M E Muller s goniometer (PROTEK AG BERN) in relation to a horizontal line through the pelvis as this modification of the angle is most commonly employed The individual results are shown in the tables of raw data on pages 79 and 80

among the first 50 per cent of the most stable hip joints there are nevertheless femoral heads which project [illegible] per cent beyond the line

Corresponding to the 50 percentile line (the median) there is a significant increase in the MP from the first to the third age group but no significant change in MP from the third to the fourth age group

Discussion

The result of the investigation corresponds to the experience of Perkins that the femoral head is completely covered by the acetabulum in children under the age of 4 years The few hips in which the femoral head extended beyond the line before the age of 4 years are perhaps »normal« but hardly »optimal«

Even though the material is cleared for children with diseases which we know result in less than perfect hip joints it is the case for all patients in this investigation that they had a manifest or suspected urological disease The material is therefore dominated by children whose hip joints are presumably less »normal« that they would have been if the children had been well

The investigation therefore does not provide an expression for »normality« but should rather be considered as indicating the »optimal« placing of the femoral head in relation to Perkins line

In this investigation all the femoral heads which lay completely within Perkins line have been given the MP value 0 per cent It will of course also be possible to indicate how deeply the femoral head is lying in relation to the acetabulum by measuring the distance from the caput femoris out to Perkins line and give this result as a percentage of the entire width of the femoral head but with a negative sign However this parameter has not been included in the present study Nevertheless a limit must be found for the permissible depth of the femoral head before it is no longer placed »optimally« but passes instead into the pathological condition protrusio acetabuli which results in osteoarthrosis (*Friedenberg* 1963 and *Hooper* & *Jones* 1971)

Moralle in 1935 was one of the authors to point out that the incongruent hip could develop into malum coxae senile — osteoarthrosis *Wiberg* in 1939 showed that a subluxated hip could lead to coxarthrosis *Bjerkreim* (1974b) showed how pronounced dysplasia of the hip in association with an oblique pelvis gave the same malformation

Following up treated cases of dislocation of the hip *Smith et al* among others showed in 1968 that poor reduction as evaluated on the radiograph resulted in osteoarthros[illegible]

[illegible]

The literature does not indicate how much or how little of the femoral head must lie outside Perkins line in childhood before the condition results in osteoarthrosis in the adult subject Before this question is investigated the »optimal« hip cannot be delimited with certainty

Conclusion

In children under the age of 4 years the observation that the femoral head was completely covered by the acetabulum in 102 out of 109 hip joints indicates that Perkins line represents the maximum lateral position for the femoral head in the »optimal« hip In children between the ages of 4 and 16 years at most 5 per cent of the visible part of the femoral head

It would be more useful to know how that hip appears in childhood which is to serve the subject *free from symptoms throughout life* in other words the »optimal« hip

The complex function of the hip joint cannot be described exhaustively by means of a single variable only In the present study this variable is the placement of the femoral head below the acetabulum as measured on an a p radiograph Experience shows however that *this is the radiographic examination* which with the least radiation dose gives the maximum amount of information on hip function *provided that mobility* is adequate and painless

Author's investigation

Urographic studies made in childhood usually also show the hip joints and as the MP can also be measured on these films this material has been selected as a starting point for the investigation

Many hundred urographs from Radiological Department X *of the Rigshospital were* examined and the hips measured From this material all patients were excluded with visible deformities of the pelvis and vertebral column including spina bifida Next all patients were excluded *with Wilms tumour and neuromuscular diseases* for example cerebral palsy *Only those hip joints were included which had been placed* in the neutral abduction adduction position during the radiological investigation

After measuring the MP the case records were reviewed for those patients in whom the femoral head *projected beyond Perkins line As a result of this review it became clear that* a large proportion of these patients had had urinary tract infection as a result of congenital malformations since the first year of life for which reason this group of patients was also excluded There remained nevertheless a number of hip joints in which the femoral head was placed laterally *in the acetabulum with squeezed acetabular rim a breach in Shenton s line* and small CE angle etc, without it being possible to find a medical etiology for this so that they were retained in the material The total remaining 355 measurements are tabulated in *the Table* on p *60*

Table 3 *Migration percentage of 355 hip joints on urographs from »normal«* children

AGE years	n	MIGRATION PERCENTAGE per cent PERCENTILES 10	50	90	100	P
< 4	108	0	0	0	14	< 0 01
4 ≤ < [illegible]	126	0	0	10	29	< 0 01
8 ≤ < 12	78	0	5	12	16	> 0 05
12 ≤ < 16	43	0	5	13	18	

Table 3 summarizes and sets out the measurements in percentiles The results are grouped into 4 year groups as a closer differentiation is not justifiable since the bone age was not determined The Table shows that in children under the age of 4 years *that part of the femoral head* visible on a radiograph is completely covered by the acetabulum in at least 90 per *cent of the hip joints Among children older* than 4 years at least 10 per cent (actually 37 per cent) of the total number of femoral heads are completely *within Perkins line but*

among the first 50 per cent of the most stable hip joints there are nevertheless femoral heads which project 5 per cent beyond the line

Corresponding to the 50 percentile line (the median) there is a significant increase in the MP from the first to the third age group but no significant change in MP from the third to the fourth age group

Discussion

The result of the investigation corresponds to the experience of Perkins, that the femoral head is completely covered by the acetabulum in children under the age of 4 years The few hips in which the femoral head extended beyond the line before the age of 4 years are perhaps »normal« but hardly »optimal«

Even though the material is cleared for children with diseases which we know result in less than perfect hip joints it is the case for all patients in this investigation that they had a manifest or suspected urological disease The material is therefore dominated by children whose hip joints are presumably less »normal« that they would have been if the children had been well

The investigation therefore does not provide an expression for »normality« but should rather be considered as indicating the »optimal« placing of the femoral head in relation to Perkins line

In this investigation all the femoral heads which lay completely within Perkins line have been given the MP value 0 per cent It will of course also be possible to indicate how deeply the femoral head is lying in relation to the acetabulum by measuring the distance from the caput femoris out to Perkins line and give this result as a percentage of the entire width of the femoral head but with a negative sign However this parameter has *not been included* in the present study Nevertheless a limit must be found for the permissible depth of the femoral head before it is no longer placed »optimally« but passes instead *into the pathological* condition protrusio acetabuli which results in osteoarthrosis (*Friedenberg* 1965 and *Hooper & Jones* 1971)

Mortille in 1933 was one of the authors to point out that the incongruent hip could develop into malum coxae senile — osteoarthrosis *Hiberg* in 1939 *showed* that a subluxated hip could lead to coxarthrosis *Bjerkreim* (1974b) showed how pronounced dysplasia of the hip in association with an oblique pelvis *gave the same* malformation

Following up treated cases of dislocation of the hip *Smith et al*, among others showed in 1968 that poor reduction as evaluated on the radiograph resulted in osteoarthrosis [illegible]

[illegible]

The complex function of the hip joint cannot be described exhaustively by means of a *single variable only In the present study this variable is the placement of the femoral head* below the acetabulum, as measured on an a p radiograph Experience shows however, that this is the radiographic examination which with the least radiation dose gives the maximum amount of information on hip function, provided that mobility is adequate and painless

Author's investigation

Urographic studies made in childhood usually also show the hip joints, and as the MP can also be measured on these films, this material has been selected as a starting point for the investigation

Many hundred urographs from Radiological Department X of the *Rigshospital were* examined and the hips measured From this material, all *patients were excluded with visible* deformities of the pelvis and vertebral column, including spina bifida Next, all patients were excluded with Wilms' tumour and neuromuscular diseases, for example cerebral palsy Only those hip joints were included which had been placed in the neutral abduction adduction position during the radiological investigation

After measuring the MP, the case records were reviewed for those patients in whom the femoral head projected beyond Perkins' line As a result of this review it became clear that a large proportion of these patients had had urinary tract infection as a result of congenital malformations since the first year of life, for which reason this group of patients was also excluded There remained nevertheless a number of hip joints in which the femoral head was *placed laterally in the acetabulum, with squeezed* acetabular rim, a breach in Shenton's line and small CE angle, etc , without it being possible to find a medical etiology for this so that they were retained in the material The total remaining 355 measurements are tabulated in the Table on p 80

Table 3 Migration percentage of 355 hip joints on urographs from »normal« children

AGE years	n	MIGRATION PERCENTAGE per cent PERCENTILES 10	50	90	100	P
< 4	108	0	0	0	14	< 0 01
4 ≤ < 8	126	0	0	10	29	< 0 01
8 ≤ - < 12	78	0	5	12	16	> 0 05
12 ≤ < 16	43	0	5	13	18	

Table 3 summarizes and sets out the measurements in percentiles The results are grouped *into 4 year groups as a* closer differentiation is not justifiable since the bone age was not determined The Table shows that in children under the age of 4 years that part of the femoral head visible on a radiograph is completely covered by the acetabulum in at least 90 per cent of the hip joints Among children older than 4 years at least 10 per cent (actually 37 *per cent)* of the total number of femoral heads are completely within Perkins line but

among the first 50 per cent of the most stable hip joints there are nevertheless femoral heads which project 5 per cent beyond the line

Corresponding to the 50 percentile line (the median) there is a significant increase in the MP from the first to the third age group but no significant change in MP from the third to the fourth age group

Discussion

The result of the investigation corresponds to the experience of Perkins that the femoral head is completely covered by the acetabulum in children under the age of 4 years The few hips in which the femoral head extended beyond the line before the age of 4 years are per haps »normal« but hardly »optimal«

Even though the material is cleared for children with diseases which we know result in less than perfect hip joints it is the case for all patients in this investigation that they had a manifest or suspected urological disease The material is therefore dominated by children whose hip joints are presumably less »normal« that they would have been if the children had been well

The investigation therefore does not provide an expression for »normality« but should rather be considered as indicating the »optimal« placing of the femoral head in relation to Perkins line

In this investigation all the femoral heads which lay completely within Perkins line have been given the MP value 0 per cent It will of course also be possible to indicate how deeply the femoral head is lying in relation to the acetabulum by measuring the distance from the caput femoris out to Perkins line and give this result as a percentage of the entire width of the femoral head but with a negative sign However, this parameter has not been included in the present study Nevertheless a limit must be found for the permissible depth of the femoral head before it is no longer placed »optimally« but passes instead into the pathological condition protrusio acetabuli which results in osteoarthrosis (*Friedenberg*, 1963 and *Hooper & Jones* 1971)

Morville in 1933 was one of the authors to point out that the incongruent hip could develop into malum coxae senile — osteoarthrosis *Wiberg* in 1939 showed that a subluxated hip could lead to coxarthrosis *Bjerkreim* (1974b) showed how pronounced dysplasia of the hip in association with an oblique pelvis gave the same malformation

Following up treated cases of dislocation of the hip *Smith et al*, among others showed in 1968 that poor reduction as evaluated on the radiograph resulted in osteoarthros[illegible]

[illegible] *be secondary to a lateralization of the femoral head as a result of the osteoarthrosis*

The literature does not indicate how much *or how little* of the femoral head must lie outside Perkins line in childhood before the condition results in osteoarthrosis in the adult subject Before this question is investigated the »optimal« hip cannot be delimited with certainty

Conclusion

In children under the age of 4 years the observa[illegible]

[illegible] the visible part of the femoral head

is lateral to Perkins line in the »optimal« hip this being the finding in 159 out of 247 hips i e not quite ⅔ This concept is only a provisional one i e until we know more about the relation between the MP and coxarthrosis

Comparison between »normal« and »abnormal« CE angles and migration percentages

In Chapter II a correlation was found between the CE angle of the hip and the MP with r = 0 76 Having now prepared a »normal« material for the MP of the hip in childhood it would be interesting to compare this material with a »normal material« based on CE angles to determine whether within the latter s limits for »normal« there is a correlation with »normal« MP and thus determine whether in spite of sources of error the CE angle can be used in childhood

Author's investigation

Massie & Howorth (1950) used the same modified CE angle as that used here These authors stated that the CE angle can be used right down to the age of 3 years and in their large »normal material« they found that the hip was normal when the CE angle was ≥ 20° for the age of 3 years and upwards

Using the same material as employed in Table 2 (raw data on pages 79 and 80) the associated values can be obtained for CE angle and MP in children over the age of 3 years

Table 4 Comparison between »normal« CE angles ≥ 20 degrees and »abnormal« CE angles < 20 degrees and corresponding migration percentage

HIP JOINTS	n		AGE ≥ 3 years	CE ANGLE degrees	MIGRATION PERCENTAGE ≥ 0	r	P
»normal«	37	median range	5^{4} 3^{5} 14^{6}	25 38 20	12 0 22	0 282	0 085
»abnormal«	66	median range	5^{7} 3^{2} 11^{2}	15 19 0	21 0 47	0 850	< 0 001

Table 4 shows that the age is the same in the two groups of CE angles »normal« and »abnormal« In the group with Massie & Howorth s »normal« hips with a CE angle ≥ 20° the correlation between CE angle and MP is very poor whereas in the group with »abnormal« hips with a CE angle < 20° the correlation gives the same value as that found for the entire material of Table 2

In the group with CE angles ≥ 20° there are hips with a MP up to 22 per cent which according to Table 3 cannot even be described as »normal« and on the basis of the conclusion on p 23 even less called »optimal« In the group with CE angles < 20° it appears that in only one hip the corresponding MP is [illegible] per cent In the rest of the hips the MPs are at least 4 per cent which corresponds to the upper limit for the »optimal« hips in children above the age of 4 years

Conclusion

A comparison between measurements of the same hip joints using CE angles and MP gave as result, that a CE angle $< 20°$ indicates that the the hip in a child above the age of 4 years is not »optimal« On the other hand, it is not possible with certainty to come to any conclusion with regard to the stability of the hip in childhood, when the CE angle $\geqslant 20°$. Correspond ing to that uncertainty the correlation between the CE angles $\geqslant 20°$ and the MP is poor

Definitions

In the literature, the terms dislocation and luxation signify that the femoral head has no contact with the acetabulum (*MacKenzie et al* 1960, *Smith et al* 1968, *Samilson et al* 1972 and *Sharrard et al* 1975) However, dislocation may also designate all degrees of lateraliza tion of the femoral head (*Harris et al* 1960)

Subluxation is most often defined as the condition in which at least one third of the femoral head lies external to the acetabulum (*Sharrard et al* 1975) Others, however, have laid down the requirement that this should be evaluated on an arthrogram (*Samilson et al* 1972)

Severin (1941) used the term subluxation only when the CE angle was negative, corre sponding to the situation in which half of the femoral head lay beyond the acetabular corner *Bjerkreim* (1974a) and *Snyder* (1975) used the term subluxation for any protrusion of the femoral head beyond the acetabulum but where contact with it was still maintained *Baker et al* (1962) classified subluxation into three degrees, in which III° corresponds with dislocation

Dysplasia may be taken to signify that the hip joint as a whole has an abnormal appear ance on a radiograph (*Wiberg* 1939 and *Baacke & Tönnis* 1974) *Medbö* (1961) used the term to signify that the femoral head extends more than 5 mm beyond the acetabulum In the study by *Sharrard et al* (1975) the term signifies that more than two thirds of the femoral head is covered by the acetabulum but with other abnormalities Dysplasia is most often used to signify a steep acetabular roof (*Sharp* 1961, *Baker et al* 1962, *Bjerkreim* 1974a and *Zsernaviczky & Turk* 1974) or all the sequelae of a subluxation (*Salter* 1970)

Discussion

It appears from the above remarks that the terms dislocation, luxation, subluxation and dysplasia are employed with varying meanings and often without being clearly defined

In children with neuromotor disease and clinically dislocated hip joints, contact with the acetabulum often is maintained medially on the radiograph When the dislocation is acquired the acetabular deformation will develop so slowly that its shape alters in parallel with the migration of the femoral head Dislocations of this kind therefore do not always satisfy the requirement that there should be a lack of contact with the acetabulum

In the terminology of descriptive radiographic diagnosis of the containment of children's hip joints the terms »nothing abnormal« and »normal« are included These terms are like wise not defined unambiguously

It might be more relevant to describe the containment by the MP instead of the usual type of diagnosis It would thus be unnecessary to procure any available earlier radiographs in order to make a comparison with the new X ray but merely to compare MPs

Conclusion

Migration Percentage (MP) signifies the fraction (expressed in per cent) of the visible part of the femoral head which on an a p radiograph has migrated beyond Perkins line (= acetabular rim) The measurements are made along a line horizontal to the pelvis

Migration is defined as the difference between two instantaneous MPs determined at two different times

Subluxation signifies that the MP is at least 33 per cent

Dislocation signifies that the MP is 100 per cent

Dysplasia is the term used during the period before the femoral head has become visible and signifies that the acetabulum is sloping with a retreating border as if it had been squeezed during growth

Recording the migration

Massie & Howorth noted in 1950 that »no roentgenographic measurement is a mathematical certainty because slight positional variations affect the readings« This still holds and has not been refuted in the preceding sections

To facilitate identifying those cases where a radiograph has been made although the hips have not been in the neutral abduction adduction position all the courses of the migration of the hips which constitute a basis for the subsequent analyses have been recorded in a co ordinate system A recording of this kind may also be used to obtain an impression of the prognosis for the migration of the hip

In Fig 5 the abscissa is time and the ordinate is MP The figure presents graphically a partly hypothetical example of the course of the migration of the hips in a child with cerebral palsy At the first radiographic examination in 1968 both femoral heads were completely covered by the acetabulum By 1969 both hips had drifted outwards so that 24 per

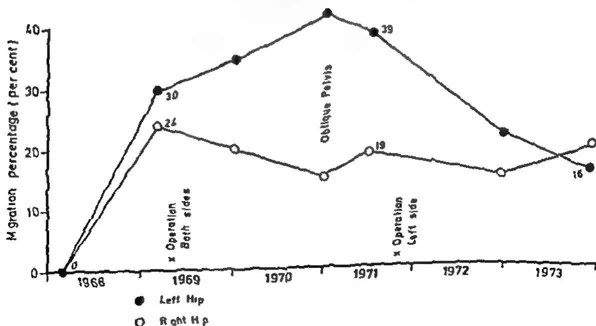

Figure 5
Migration percentage in relation to time before and after operations in a hypothetical case

cent of the right femoral head and 30 per cent of the left femoral head had moved beyond Perkins line As a result of the operation which followed the MP of the hips were altered The right hip moved inwards and the left hip moved slowly outwards The MP remained divergent until the middle of 1971 at which time the MPs were 19 per cent and 39 per cent

When the hips show a change in direction on the curve without preceding treatment the MPs beginning to converge instead of diverge this usually means that the more divergent measurements have been made with the pelvis oblique In the present case the right hip has been abducted and the left hip adducted for which reason no value can be attached to such a measurement However there may be such pronounced contractures in the abductors or adductors that the pelvis cannot be placed in a neutral position Such faulty positions will not be noticed on the curves as no change will be observed in the slope of the curves so long as the contractures remain untreated Measurements from such records are not rejected

Following the next operation this time on the left hip this hip too moved inwards and in 1975 was found to have a MP of 16 per cent

In order to visualize those changes in the MP of the hips resulting from treatment a coordinate system may be used with the same units in both coordinates (*Freeman et al* 1973 and *Collert* 1974)

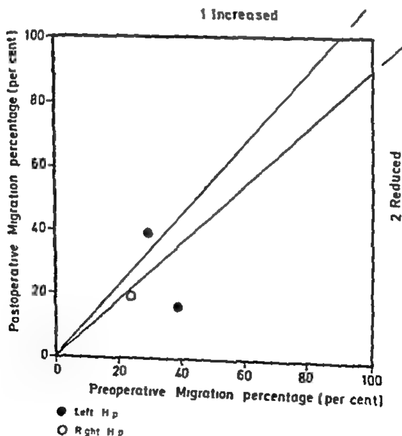

Figure 6
Diagram illustrating the difference in migration percentage before and after the operations in Fig 5

Conclusion

Migration Percentage (MP) signifies the fraction (expressed in per cent) of the visible part of the femoral head which on an a p radiograph has migrated beyond Perkins line (= acetabular rim) The measurements are made along a line horizontal to the pelvis

Migration is defined as the difference between two instantaneous MPs determined at two different times

Subluxation signifies that the MP is at least 33 per cent

Dislocation signifies that the MP is 100 per cent

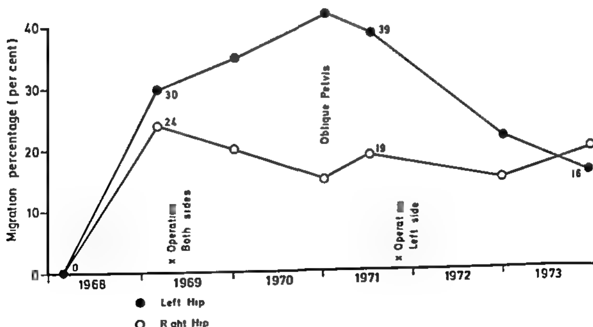
Dysplasia is the term used during the period before the femoral head has become visible and signifies that the acetabulum is sloping with a retreating border, as if it had been squeezed during growth

Recording the migration

Massie & Howorth noted in 1950 that »no roentgenographic measurement is a mathematical certainty, because slight positional variations affect the readings« This still holds and has not been refuted in the preceding sections

To facilitate identifying those cases where a radiograph has been made although the hips have not been in the neutral abduction adduction position all the courses of the migration of the hips which constitute a basis for the subsequent analyses have been recorded in a co ordinate system A recording of this kind may also be used to obtain an impression of the prognosis for the migration of the hip

In Fig 5 the abscissa is time and the ordinate is MP The figure presents graphically a partly hypothetical example of the course of the migration of the hips in a child with cere bral palsy At the first radiographic examination in 1968 both femoral heads were com pletely covered by the acetabulum By 1969 both hips had drifted outwards so that 24 per



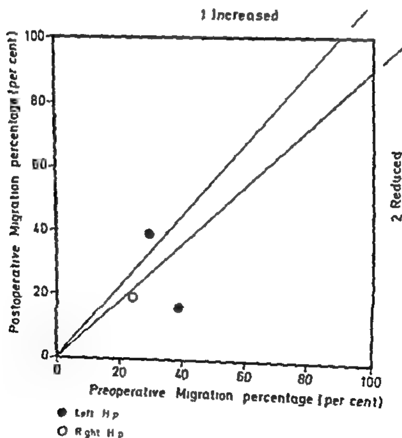


Figure 5
Migration percentage in relation to time before and after operations in a hypothetical case

cent of the right femoral head and 30 per cent of the left femoral head had moved beyond Perkins line As a result of the operation which followed the MP of the hips were altered The right hip moved inwards and the left hip moved slowly outwards The MP remained divergent until the middle of 1971 at which time the MPs were [illegible] per cent and 39 per cent When the h ps show a change in direction on the curve without preceding treatment the [illegible]

a measurement However there may be such pronounced contractures in the abductors or adductors that the pelvis cannot be placed in a neutral position Such faulty positions will not be noticed on the curves as no change will be observed in the slope of the curves so long as the contractures remain untreated Measurements from such records are not rejected

Following the next operation this time on the left hip this hip too moved inwards and in 1973 was found to have a MP of 16 per cent

[illegible] a coordi [illegible] 1973 and *Collert* 1974)

F gure 6
Diagram illustrat ng the d fference in m gration percentage before and after the operations in F g 5

In Fig 6, the MPs have been inserted for the two hip joints from the above example, just before the three operations and on follow up examination or just before the next operation *It is obvious that the coordinate area is divided into two regions the upper including all hips* where there has been an increase in MP, the lower all hips where there has been a reduction in MP To make allowance for uncertainty in the results, the diagonal separating the two regions is replaced by two lines embracing an area of ± 10 per cent of the actual values obtained

Fig 6 shows that the right hip lies in the region of reduced MP, as the MP in 1969 was 24 per cent, and post operatively, just before the next operation i 1971, it was 19 per cent The left *hip lies both in the upper region as the MP had increased in spite of the treatment in 1969* and in the lower region corresponding to the result of reoperation in 1971

The constructed example shows changes in MP from just before to just after the operation The diagram can be used in a similar manner to illustrate the course of hip migration either before or after operation (Fig 5 shows that before the right hip was operated on the MP changed from 0 per cent to 24 per cent and after operation from 24 per cent to 19 per cent) Both methods of representation will be used in the next section

Chapter IV

Spontaneous migration

One aim of this study is to examine whether subluxation of the hip joint in cerebral palsy is most frequently an acquired condition This presupposes that the spontaneous migration of the »normal« hip is known and that subluxation does not occur in the »normal« hip

The »normal« hip

The spontaneous migration occurring throughout the years of childhood can be seen directly from Table 3 This »normal material« shows that the median (the 50 percentile) value of the MP varies from 0 per cent in children under the age of 4 years to 5 per cent in children betwen 12 years and 16 years The difference is significant Table 3 also shows that none of the 355 hip joints were found subluxated

Conclusion

The migration of the »normal« hip in children is less than 1 per cent per annum The »normal« hip in children does not undergo subluxation

The »cerebral-palsy« hip

Since *Ludloff* in 1902 described a case of bilateral dislocation of the hip in a girl with Little's disease the subject has been often discussed *Wollenberg* in 1908 stated that it was difficult to demonstrate that the dislocation is a direct sequela to cerebral palsy However the literature contains terms such as dislocating luxating subluxating and migrating hips as an indication that experience has made it clear that subluxation and dislocation may be acquired The same is suggested by the many communications on the causes of dislocation (e g *Klopfer* 1950 *Mau* 1951 *Phelps* 1959 *Lamp & Pollock* 1962) and on its prophylaxis (e g *Gaugele* 1906 *Pollock & Sharrard* 1958 *Bank & Green* 1960 and *Jones* 1962)

In spite of the many investigations carried out it has not been possible to find one study which provides proof that the subluxated hip in cerebral palsy is in fact acquired, and not a congenital deformity

Author's investigation

Surgical treatment of the sequelae of cerebral palsy was carried out in the case of 441 patients admitted to Department 1 of the *Orthopaedic Hospital* Copenhagen during the period 1st January 1969 to 1st July 1971 In this total there were 127 children under the age of 19 years who underwent a total of 218 adductor operations during the period possibly combined with other operations but exclusive of operations on the hamstrings or osteotomy

of the femur Among these 127 children there were a total of 38 children who within the period mentioned had had a MP of at least 33 per cent (= subluxation) in one or both hips

Based on radiographs from a number of hospitals and institutions, curves were drawn of the course of hip migration Any operations on the adductors prior to 1969 were included in the investigation

In 39 cases out of 63 first time operations on the adductors, not only was a usable radiograph of the hip found preoperatively, but also at least 3 months prior to this, so that the preoperative migration of the untreated hips could be recorded on a diagram, as shown in Fig 7 In this investigation the earliest radiograph which could be traced was used (raw data on p 81)

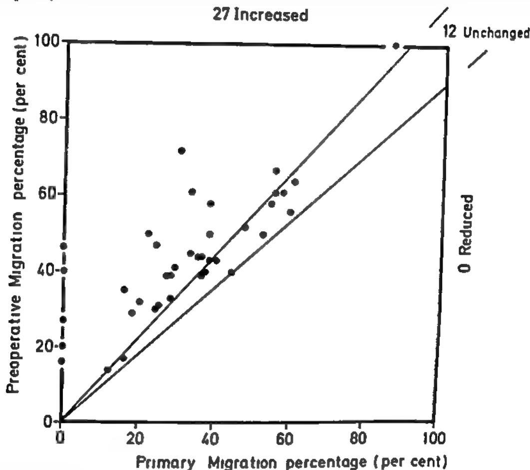

Figure 7
Spontaneous migration of 39 »cerebral palsy« hips

Fig 7 shows that 27 hips had migrated outwards in relation to Perkins line 12 hips had remained unchanged and no hips had migrated inwards

From the time the primary radiograph of the hips was made to the time the preoperative radiological investigation was performed 5 hips which primarily had been completely covered by the acetabulum had migrated beyond Perkins line 16 per cent 20 27 40 and 46 per cent respectively while 10 hips had become subluxated and 1 hip had become dislocated

Table 5 summarizes the MPs for all 39 hips The table shows that the median value for the MP on the primary radiograph was 33 per cent and just before the first adductor operation it was 43 per cent This difference is significant with $P < 0\ 001$ The period of observation had a median value of 1 year

Table 5 Migration percentage before first operation on the adductors

Conclusion

In agreement with clinical experience the investigation shows that the subluxated hip in

the time of operation 10 of the hips had subluxated during the course of the period of observation a median interval of 1 year 3) the »normal« hip does not subluxate 4) none of the »cerebral palsy« hips improved spontaneously

Postoperative migration

The »cerebral palsy« hip

The literature has often described how the femoral head may m grate
operations on muscles and tendons (e g *Watson Jones*
al 1962 *Samilson et al* 1967 *Ingram* 1971 *Samilson e*
These accounts however have not demonstrated at the same time that it was the hip joint which previously migrating outwards had now improved after and possibly as a result of the operations *Sharrard et al* (1975) however did mention that subluxations could arise during the waiting period prior to admission for operation

Before analyzing in further detail the separate factors influencing the position of the hip in the acetabulum there are therefore grounds for demonstrating that alone by surgery of muscles and tendons it is possible to influence the MP and to show the degree to which this is possible

The effect of first operation on the adductors

In the present material adductor surgery is performed through a transverse incision in the groin over the adductor longus tendon The tendons and muscles of the adductors are d vided proximally so that all structures are transected which hinder normal abduction with the hip both flexed and extended The operation also often includes tenotomy of the m gracilis in the groin or resection proximal to the knee If the spasticity has been pro nounced in the adductors the anterior branch of the obturator nerve is resected and where important h p flexion contracture has been found preoperatively the iliopsoas is also di

Conclusion

In agreement with clinical experience the investigation shows that the subluxated hip in cerebral palsy is most often acquired since 1) the spontaneous migration of approximately 10 per cent per annum is significantly greater than the migration of less than 1 per cent per annum in the case of the »normal« hip 2) of the total of 30 hips which were subluxated at the time of operation 10 of the hips had subluxated during the course of the period of observation a median interval of 1 year 3) the »normal« hip does not subluxate 4) none of the »cerebral palsy« hips improved spontaneously

Postoperative migration

The »cerebral palsy« hip

The literature has often described how the femoral head may migrate inwards following operations on muscles and tendons (e g *Watson Jones* 1926 *Banks & Green* 1960 *Baker et al* 1962 *Samilson et al* 1967 *Ingram* 1971 *Samilson et al* 1972 and *Sharrard et al* 1975) These accounts however have not demonstrated at the same time that it was the hip joint *which previously* migrating outwards had now *improved* after and possibly as a result of the operations *Sharrard et al* (1975) however did mention that subluxations could arise during the waiting period prior to admission for operation

Before analyzing in further detail the separate factors influencing the position of the hip in the acetabulum there are therefore grounds for demonstrating that alone by surgery of muscles and tendons it is possible to influence the MP and to show the degree to which this is possible

The effect of first operation on the adductors

In the present material adductor surgery is performed through a transverse incision in the groin over the adductor longus tendon The tendons and muscles of the adductors are divided proximally so that all structures *are transected* which hinder normal abduction with the hip both flexed and extended The operation also often includes tenotomy of the m gracilis in the groin or resection *proximal to the knee* If the spasticity has been pronounced in the adductors the *anterior* branch of the obturator nerve is resected and where important hip flexion contracture has been found *preoperatively* the iliopsoas is also di

vided near the attachment to the trochanter minor. Postoperatively the patients were immobilized in abduction in a plaster cast for 3 weeks, followed by night splinting in abduction.

Author's investigation

The same material of »cerebral palsy« hips in which the spontaneous migration was demonstrated, was subjected to measurement following the operation. The hips were measured on the latest useful radiograph prior to any possible subsequent operation, and latest on the 1st November 1973, which was selected as the termination date of the investigation (raw data on p. 81).

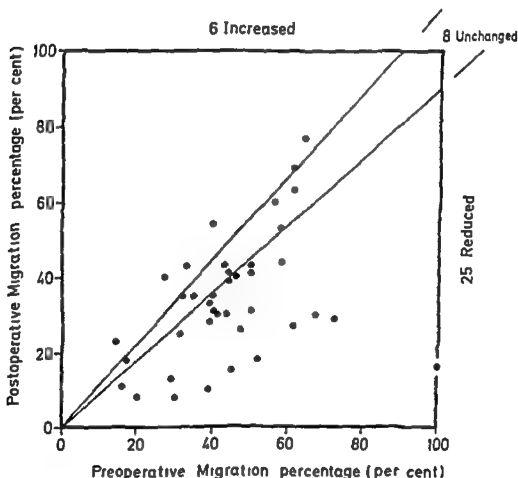

Figure 8
Migration of 39 »cerebral palsy« hips after first operation on the adductors

Fig 8 shows that after the operation the MP was reduced in 25 of the hips, 8 of the hips were unchanged, and 6 of them had an increased MP The hip which was previously dislocated had been reduced as a result of operation, so that only 18 per cent of the femoral head now reached beyond Perkins' line The figure also shows that the improvement was distributed uniformly and did not apply only to the subluxated hips with a MP of at least 33 per cent A comparison with Fig 7 shows immediately that the operation has influenced the migration in a favourable direction

Table 6 Migration percentage before and after first operation on the adductors with preoperative observation

n = 39	MIGRATION PERCENTAGE per cent		
	PRIM	PREOP	POSTOP
median	33	45	31
range	0 86	14 100	8 77

P < 0 001 P < 0 001

Table 6 summarizes the MPs of the hips before and after operation Following the operation the median value of the MP decreased from a preoperative value of 45 per cent to a post operative value of 31 per cent This corresponds to a migration before operation of 10 per cent outwards and after operation of 12 per cent inwards The difference between the MPs is significant P < 0 001

Conclusion

This investigation shows that in patients with cerebral palsy the hip joint migrating out wards can often be made to migrate inwards following an operation on the adductors pos sibly in combination with some other soft tissue procedures

Result of first operation on the adductors

Sharrard et al in 1975 analyzed the results which had been obtained in 154 hips by soft tissue procedures including adductor release and showed that operation on the adductors can often change a »dysplastic« hip into a normal hip while a subluxated hip usually con tinues to show some »dysplastic« features They therefore advised early operation and found that in 75 per cent of the cases one operative procedure on the adductors succeeded in ob taining or maintaining hip stability

Another thorough study of the effect of operation on the adductors was made by *Samilson et al* in 1967 However as their treatment included osteotomies on the femora the results cannot be compared with the results following soft tissue procedures alone

An attempt to confirm the conclusions reached by Sharrard et al would thus seem in dicated

Author's investigation

Table 6 shows that the primary median MP before and postoperative median MP after the first adductor operation are almost identical This must *signify* that the improvement gained as a result of the operation corresponds *numerically to the* increase in MP during the period of observation from the time the primary radiograph was taken until the operation took place This suggests that instead of allowing a period of observation to elapse there should have been surgical intervention *immediately*

In the »adductor material« on p 30 there are a further 18 hips for which only a pre operative radiograph was available prior to the *first adductor operation* and not a primary

vided near the attachment to the trochanter minor Postoperatively the patients were immobilized in abduction in a plaster cast for 3 weeks followed by night splinting in abduction

Author's investigation

The same material of »cerebral palsy« hips in which the spontaneous migration was demonstrated was subjected to measurement following the operation The hips were measured on the latest useful radiograph prior to any possible subsequent operation and latest on the 1st November 1973 which was selected as the termination date of the investigation (raw data on p 81)

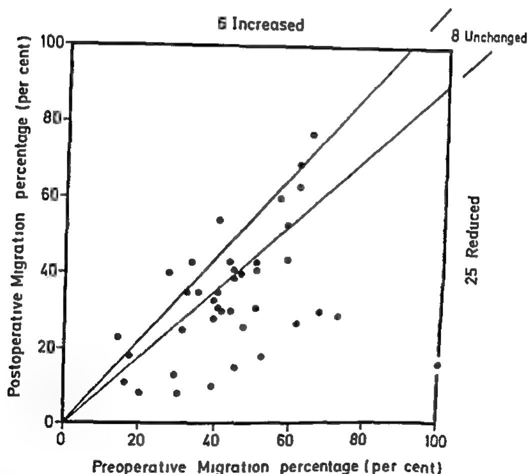

Figure 8
Migration of 39 »cerebral palsy« hips after first operation on the adductors

Fig 8 shows that after the operation the MP was reduced in 25 of the hips 8 of the hips were unchanged and 6 of them had an increased MP The hip which was previously dislocated had been reduced as a result of operation so that only 18 per cent of the femoral head now reached beyond Perkins line The figure also shows that the improvement was distributed uniformly and did not apply only to the subluxated hips with a MP of at least 33 per cent A comparison with Fig 7 shows immediately that the operation has influenced the migration in a favourable direction

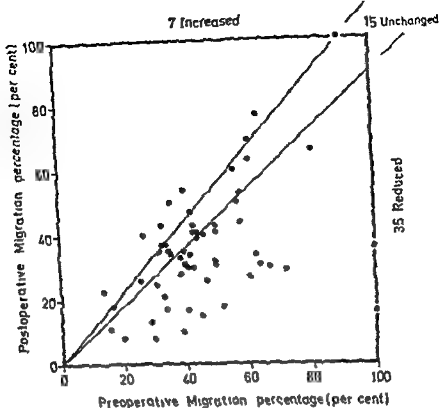

Figure 9
Migration of 57 »cerebral palsy» hips with and without preoperative observation after first operation on the adductors

wards in 69 per cent of the 39 hips before operation and that after operation 12 per cent of the 57 hips still migrated outwards This means that 57 per cent of the hips are seen to have improved or unchanged stability as a sequel to operation

Table 9 Spontaneous migration compared with postoperative migration

MIGRATION	n	NUMBER OF HIPS WITH INCREASED MIGRATION PERCENTAGE	UNCHANGED MIGRATION PERCENTAGE	REDUCED MIGRATION PERCENTAGE
Spontaneous	39	27 = 69%	12 = 31%	0
Postoperative	57	7 = 12%	15 = 26%	35 = 61%

Conclusion

This investigation confirms the finding of *Sharrard et al* (1975) that the *first operation* on spastic adductors results in the position of the femoral head in relation to the acetabulum being maintained or improved in 57 per cent of the cases (Sharrard et al achieved 75 per

radiograph as the patients underwent surgery without a period of observation as soon as it was established that at least one of the hips was subluxated *As the material of Sharrard et al* (1975) does not record preoperative migration of the hips the above hips can be included in the material compared with Sharrard s material provided their data do not deviate essen tially from those of the 39 hips whose *preoperative course was followed (raw data on p 82)*

Table 7 Migration percentage before and *after first operation on the adductors* without preoperative observation

n = 18	MIGRATION PERCENTAGE per cent	
	PREOP	POSTOP
median	42	35
range	*26-100*	*17-100*

$P < 0\ 001$

Table 7 summarizes the measurements of the MPs of the 18 hips after the adductor opera tion The median value of the MP was 42 per cent preoperatively and 35 per cent post operatively *This difference is significant with $P < 0\ 001$ and corresponds to a migration of 7* per cent

A comparison with the preoperative MP value in Table 6 shows that as the preoperative MP is by chance nearly the same and *as the postoperative MP does not differ significantly* from that in Table 7, the results from the two Tables have been added in Table 8

Table 8 Migration percentage before and after first operation on the adductors with and without preoperative observation

n = 57	MIGRATION PERCENTAGE per cent	
	PREOP	POSTOP
median	43	34
range	14 100	8 100

$P < 0\ 001$

The total of hips followed up after the first adductor operation is now 57 and Table 8 shows that they have been significantly improved ($P < 0\ 001$)

The result of the 57 adductor operations are visualized in Fig 9 As the diagram shows 35 hips were improved 15 were unchanged and 7 had an increased MP in spite of the opera tion

On the assumption that the preoperative course for the patients who did not undergo

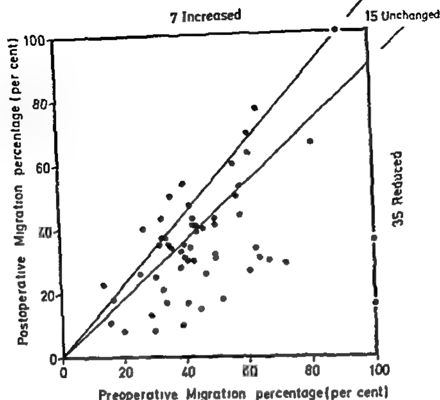

Figure 9
Migration of 57 »cerebral palsy« hips with and without preoperative observation after first operation on the adductors

wards in 69 per cent of the 39 hips before operation and that after operation 12 per cent of the 57 hips still migrated outwards This means that 57 per cent of the hips are seen to have improved or unchanged stability as a sequel to operation

Table 9 Spontaneous migration compared with postoperative migration

MIGRATION	n	NUMBER OF HIPS WITH INCREASED MIGRATION PERCENTAGE	UNCHANGED MIGRATION PERCENTAGE	REDUCED MIGRATION PERCENTAGE
Spontaneous	39	27 = 69%	12 = 31%	0
Postoperative	57	7 = 12%	15 = 26%	35 = 61%

Conclusion

This investigation confirms the finding of *Sharrard et al* (1975) that the first operation on spastic adductors results in the position of the femoral head in relation to the acetabulum being maintained or improved in 57 per cent of the cases (Sharrard et al achieved 75 per

cent) In addition the investigation confirms that if the decision as to treatment is to be based alone on an evaluation of the radiograph of the hips operation should be carried out as soon as a commencing subluxation has been identified since the first operation on the adductors cannot result in an optimal state of the hips if they are subluxated in advance and since the hips do not improve spontaneously

Result of all muscle operations

The account by Sharrard et al of operations to maintain hip stability includes femoral osteotomy in the final results From these results therefore it is still not possible to determine how far soft tissue procedures alone will maintain the stability of the hip

It is known that soft tissue operations for the sequelae of cerebral palsy have a high relapse frequency Thus even though as shown above a satisfactory result is obtained in 57 per cent of the hips after the first adductor operation it is nevertheless conceivable on a long term view that the desired results are not achieved with regard to preserving the stability of the hip

It was therefore found reasonable to examine the magnitude of the effect on the hip stability of soft tissue procedures alone both in relation to the first radiograph available of the patient s hips and in relation to the maximum hip migration percentage

Author's investigation

The »adductor material« on p 30 included 38 children who during the period 1st January 1969 to 1st July 1971 presented a definitely pathological hip joint These children underwent at least one adductor operation in one or both legs during the period in question These children were followed up measurements being made on subsequent radiographs Where osteotomies were performed on femora or pelvis measurements were made on the last radiograph prior to the bone surgery

Two children had to be omitted from the material one child because no radiographic examination of the hips had been made prior to the first adductor surgery while the other child died 7 months after operation without a control radiograph having been made (raw data on p 83 and 84)

Table 10 Result of all muscle operations *in relation to the primary and the maximal migration percentage*

n = 72	AGE years FINAL	OBSERVATION years	MIGRATION PERCENTAGE per cent PRIMARY	FINAL	MAXIMAL
median	10^{1}	6^{7}	31 5	26 5	44
range	5^{3} 23^{4}	1^{3} 18^{8}	0 100	7 100	15 100
			P > 0 1		P < 0 001

Table 10 shows that the median value for the primary MP was 31 5 per cent After a median observation period of 6[7] years the MP was reduced to 26 5 per cent This difference is not significant P > 0 1

In relation to the maximum MP with a median value of 44 per cent which the hips have experienced in the course of the observation period the result of the operations has been to improve the hip stability to a median MP of 26 5 per cent This result is significant as P < 0 001

At the time of the final observation the patients were between 5[5] years and 23[4] years old with a median age of 10[1] years Nine of the patients were over the age of 12 years

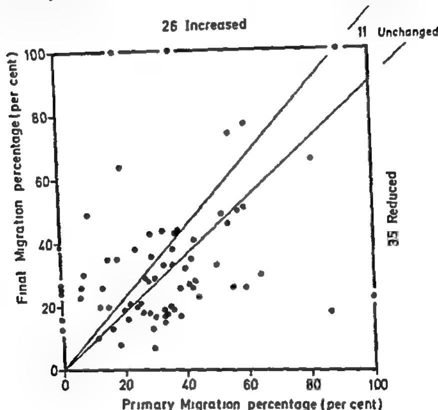

Figure 10
Migration after all muscle operations in relation to the primary migration percentage

Fig 10 visualizes the results of the operations in relation to the primary radiograph of the children taken before the first operation 35 hips were improved 11 hips remained unchanged and 26 hips increased their MP in spite of the operations Three hips dislocated

Fig 7 on p 30 shows the spontaneous migration of the »cerebral palsy« hips It is seen here that 27 out of 39 hips (= 69 per cent) migrated outwards Compared with Fig 10 it is seen that 26 out of 72 hips (= 36 per cent) migrated outwards after the muscle operations This means that on the long term view the muscle operations have had the effect of improving the stability in 69 per cent 36 per cent − 33 per cent of the hip joints

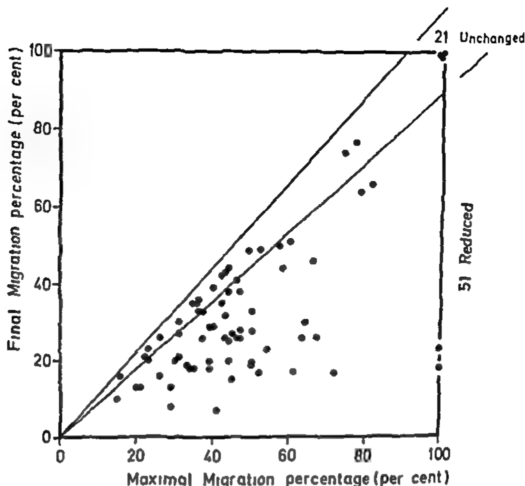

Figure 11
Migration after all muscle operations in relation to the maximal migration percentage

Fig 11 visualizes the results starting from the maximum MP experienced by the hips during the period of observation so that none of the hips increased their MP and 51 (= 71 per cent) developed better stability Two of the hips which at one time were dislocated migrated inwards to points 18 per cent and 23 per cent external to Perkins line

Table 11 Procedures in 36 children with cerebral palsy in the course of 87 hospitalizations during a period of observation with a median extent of 6[7] years

Operations	n
Adductor release	91
Gracilis resection	83
Obturator anterior neurectomy	40
Hip flexor elongation	14
Hamstrings elongation	24
Abductor release	4
Yount s operation	3
Rectus elongation	5
Achilles tendon elongation	26

Table 11 reviews the number of individual interventions carried out in these 72 hip joints Only 63 of the hips underwent adductor surgery so that in the course of 6½ years an average of 1 4 operations were performed for each hip treated Several of the hips under went up to three adductor operations however as well as two resections of n obturatorius in order to retain stability The operations carried out during the course of 87 admissions to hospital

In 9 cases varus osteotomies of the femur were performed later and in two cases a pelvic osteotomy by the method of Chiari

Conclusion

In this investigation where 72 »cerebral palsy« hips were followed through several years (median period 6[7] years) it was shown that by operations on the hip adductors including [illegible]

By comparison with the maximum MP during the course of the period the operations have resulted in an improvement in stability in 71 per cent of the hips

General discussion

A satisfactory investigation depends just as much on an adequate patient material as on adequate methods of measurement

In this study it would have been an optimum condition if from a definite date the children could have been followed by means of radiographs every 6 months for example until a number of the hips had subluxated and if surgical correction had been carried out only then This is not possible on ethical grounds

The study by *Sharrard et al* (1975) is based on those patients who had previously undergone treatment who attended for examination again i 1973 The radiographs made and the operations performed were analyzed retrospectively without any guarantee that patients whose hips had possibly dislocated in spite of the treatment had defaulted from control because others had formed an estimate that the children could not now be treated orthopaedically This may explain why Sharrard et al s material does not include children with dislocated hips in the operated group

Contrary to this in the material of *Samilson et al* from 1967 there were 41 dislocated hips before operation and after treatment 26 of these were still dislocated In addition 7 out of 169 stable hips were dislocated in spite of operations including femoral osteotomies

In the present study where the primary aim was among other things to examine whether soft tissue surgery has an effect on the stability of the hip the starting material has been all those cases with subluxated hips which were operated on during a definite period These patients were then studied prospectively and retrospectively as a result of which it was possible in spite of lack of radiographs of the hips to collect a s [illegible] in the other two cases no indications were found for suggesting further treatment

It might seem remarkable that as a result of the first adductor operation 57 per cent improved in the first instance whereas the long term result often after several operations was about 33 per cent

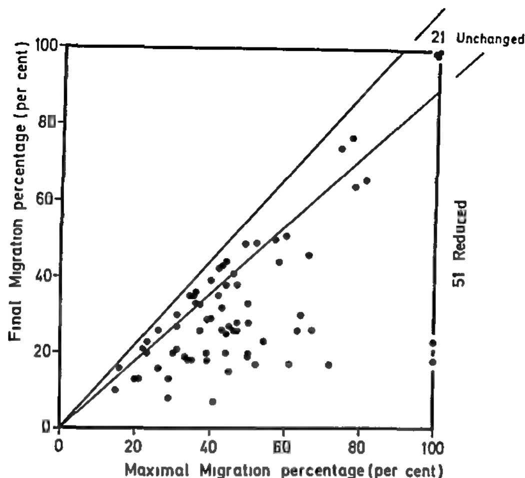

Figure 11
Migration after all muscle operations in relation to the maximal migration percentage

Fig 11 visualizes the results starting from the maximum MP experienced by the hips during the period of observation so that none of the hips increased their MP and 51 (= 71 per cent) developed better stability Two of the hips which at one time were dislocated migrated inwards to points 18 per cent and 23 per cent external to Perkins line

Chapter V

Result of single operations

It was shown in the last chapter how the MP may decrease following adductor operation This however was often combined with other forms of soft tissue interventions It would therefore be desirable to analyze if possible the part played by such operations alone so as to obtain an impression of their contribution to the results

Migration index

In earlier analyses no allowance was made for the duration of the period of observation but it was merely noted whether the MP had increased in relation to operation If however it is a question of comparing the results of different operations by means of the magnitude of the MP it is necessary to allow for the time elapsed from the primary radiograph to the pre operative radiograph and again from the operation to the postoperative radiograph in order to obtain results which can be evaluated quantitatively

The concept *Migration Index (MI)* is therefore introduced giving the change in the MP in one year The MI has a negative sign if the femoral head migrates outwards in relation to Perkins line and a positive sign if it migrates inwards The difference between the post operative and preoperative MI then gives an indication of the *Result of the Treatment*

Example
The primary radiograph shows a MP of 20 per cent 18 months later the preoperative radiograph shows that the MP has become 30 per cent The MI is therefore (20 30) $\times \frac{12}{18}$ – 7 per cent/year The MP five years postoperatively was measured as 40 per cent so that the MI now is (30 40) $\times \frac{12}{60}$ – 2 per cent/year i e the h p is still migrating outwards after the operation but more slowly than before the operation The Result of the intervention is thus 2 (7) 5 per cent/year This signifies that the migration after treatment is 5 per cent less annually than it was before the operation or in other words each year the acetabulum covers 5 per cent more of the femoral head that it would have done without the operation

It is not possible to quote a MI of 7 per cent/year for the individual hip since the measure ment uncertainty is so great and in addition there is uncertainty as to whether the migra tion is linear However if the method is used for a larger number of hips before and after treatment the statistical analysis of the Results permits the uncertainty to be ignored

M. gracilis resection

[illegible]

intervention [illegible] the m gracilis as an isolated

Assuming that it is a muscular imbalance which deforms the hip this may be explained by the elongated muscles being weakest immediately after an operation In the course of the child s continued growth the muscles regain some of their function when once more they become relatively shorter In those cases where the cerebral lesion and external circum stances in the form of effectiveness of training permit improved function of the antagonists to the muscles operated on may be achieved in the postoperative period If this improved function is not achieved after the first operation it seems as if the chance of this succeeding after the next operation is considerably less On the other hand if the hip deformation is due to a contracture the difference in operational results can be explained by the con tracture recurring because of inadequate postoperative prophylaxis

Although the aim of the present study has not been to elucidate the functional capacity of the children before and after the operations the question must be discussed here whether the result has been worth the efforts invested

If on Fig 11 a vertical line is drawn corresponding to the maximum MP of 50 per cent it is seen that of the total of 25 hips that had a greater MP than this before operation 20 have had a reduced MP after operation i e have obtained better stability contrary to what is known from experience that a »cerebral palsy« hip dislocates rapidly when only half of the femoral head is covered by the acetabulum which at that time is usually narrow and steep A possible explanation of the accelerated migration is the demonstration by *Fujiuara et al* in 1974 that there is greater electromyographic activity in more muscle groups around the hips in subluxation than in concentric hips or in dislocation

Experience as well as the reports in the literature show that dislocation in cerebral palsy patients is often accompanied by pain and in any case deterioration in general function to gether with nursing problems (*Weber* 1911 *Watson Jones* 1926 *Pollock & Sharrard* 1958 *Jones* 1962 *Ducharme* 1967 and *Samilson et al* 1972) In agreement with other authors (*Samilson et al* 1972 and *Sharrard et al* 1975) we therefore feel that these considerations justify the intervention independent of grade of intelligence and the ambulatory status

General conclusion

The preceding investigations have shown that in cerebral palsy the subluxated hip is most often acquired Such hips do not improve spontaneously Following an adductor operation possibly combined with other operations on muscles and tendons stability may be expected to be maintained or improved in 57 per cent of the hips

In 72 hips followed over a period of median 6^7 years stability was found to be retained or improved in about 33 per cent of the hips possibly after repeated operations

Among the 25 hips projecting more than 50 per cent beyond the roof of the acetabulum soft tissue procedures alone achieved a better stability in 80 per cent of the hips

The results indicate that the hips in this category of patients should receive operative treatment and the radiological results are better if treatment is instituted without allowing a period of observation to elapse once the head of the femur has been observed to be sub luxated At the same time the hips should be examined radiologically and the MP mea sured as soon as the diagnosis of cerebral palsy is made

Chapter V

Result of single operations

It was shown in the last chapter how the MP may decrease following adductor operation This however was often combined with other forms of soft tissue interventions It would therefore be desirable to analyze if possible the part played by such operations alone so as to obtain an impression of their contribution to the results

Migration index

In earlier analyses no allowance was made for the duration of the period of observation, but it was merely noted whether the MP had [illegible]

[illegible]

operative radiograph and again from the operation to the postoperative radiograph in order to obtain results which can be evaluated quantitatively

The concept *Migration Index (MI)* is therefore introduced giving the change in the MP in one year The MI has a negative sign if the femoral head migrates outwards in relation to Perkins line and a positive sign if it migrates inwards The difference between the post operative and preoperative MI then gives an indication of the *Result of the Treatment*

Example
The primary radiograph shows a MP of 70 per cen[illegible] 18 m[illegible]
that the MP has become 30 per cent T[illegible]
five years postoperatively was measurec[illegible]
cent year i e the hip is still migrating [illegible] after the operation but more slowly than before the operation The Result of the intervention is thus 2 (7) = 5 per cent/year This signifies that the migration after treatment is 5 per cent less annually than it was before the operation or in other words each year the acetabulum covers 5 per cent more of the femoral head that it would have done without the operation

It is not possible to quote a MI of 7 per cent/year for the individual hip since the measure ment uncertainty is so great and in addition there is uncertainty as to whether the migra tion is linear However if the method is used for a larger number of hips before and after treatment the statistical analysis of the Results permits the uncertainty to be ignored

M. gracilis resection

The [illegible]
wher[illegible]
bral[illegible]
cont[illegible]
intervention [illegible] to lengthen the m gracilis as an isolated

Before 1969 the operation was usually carried out medially on the femur just proximal to the knee by resecting 1 cm of the tendon and the peritendinum After 1969 if operation was combined with an adductor operation the procedure included myotomy of the m gracilis at its origin on the ramus inferior ossis pubis The effect of the two operation variations must be the same

Author's investigation

A total of about 1700 children with cerebral palsy received treatment in the Outpatients Department for Handicapped Children the Rigshospital during the period 1950 to 1976 The case records were reviewed to extract all those patients satisfying the condition that not only should there be a preoperative radiograph of the hips but also a primary and a postoperative radiograph made at least 5 months before and after operation respectively A total of 10 patients were found who satisfied these requirements having undergone a total of 19 single gracilis resections The MP was determined and recorded on curves (raw data p 85)

Table 12 Result of m gracilis recection in 19 hip joints

n = 19	AGE years	OBSERVATION years		MIGRATION PERCENTAGE per cent			RESULT per cent/year

$P > 0\ 1$

Table 12 *summarizes the measurements and shows that the overall median Result of the m* gracilis resections was 2 per cent/year evaluated from the raw data of the MIs before and after operation The Result is not significant as $P > 0\ 1$

The outwards migration before operation changed from a median value of 15 per cent to a median value of 21 per cent in the course of 1^{6} years and then ceased the MP 1^{4} years after the operation being 22 per cent

N. obturatorius resection

The anterior branch of the nerve supplies *mainly the mm adductor longus and brevis* and the m gracilis with motor branches but because of accessory branches and communication with other nerve branches the area of innervation is not stable This is now the last neurectomy still employed since the days when it was common to employ a variety of neurectomies (*Vulpius & Stoffel* 1913)

Because of risk of paralysis of the adductors *and in consequence* contracture in the abductors (*Silver et al* 1966) only a single total obturator neurectomy has been performed in Copenhagen *Hagberg et al* in 1964 analyzed the results following total obturator neurectomy in 41 children with cerebral palsy but they did not mention the possible effect on the stability of the hip

Anterior neurectomy is usually *performed in* connection with adductor tenotomy 1 cm of

the anterior branch of the obturator nerve being resected Care is taken that this is the nerve branch either by electrical stimulation or merely by pinching the nerve which results in a brief contraction of the associated muscles Microscopic identification of the nerve was not ensured in all operations The anterior branch of the nerve has a tendency to partial re generation while becoming thicker at the same time Microscopy shows degenerative changes with fibrous splitting and the formation of neuromata Among the 38 children with subluxation of the hip mentioned on p 30 there are 4 cases where the nerve was resected twice

Author's investigation

The material from the Rigshospital was found to include 6 single neurectomies and 4 operations which were combined with m gracilis resection As the Result following gracilis resection alone is known from previous investigations these 4 cases were included (raw data on p 85)

Table 13 Result of anterior obturator neurectomy in 10 hip joints

P > 0 1

Table 12 summarizes the measurements and shows that the overall median Result of the m gracilis resections was 2 per cent/year evaluated from the raw data of the MIs before and after operation The Result is not significant as P > 0 1

The outwards migration before operation changed from a median value of 15 per cent to a median value of 21 per cent in the course of 1^6 years and then ceased the MP 1^4 years after the operation being 22 per cent

N. obturatorius resection

The anterior branch of the nerve supplies mainly the mm adductor longus and brevis and the m gracilis with motor branches but because of accessory branches and communication with other nerve branches the area of innervation is not stable This is now the last neurectomy still employed since the days when it was common to employ a variety of neurectomies (*Vulpius & Stoffel* 1913)

Because of risk of paralysis of the adductors and in consequence contracture in the abductors (*Silver et al* 1966) only a single total obturator neurectomy has been performed in Copenhagen *Hagberg et al* in 1964 analyzed the results following total obturator neurectomy in 41 children with cerebral palsy but they did not mention the possible effect on the stability of the hip

Anterior neurectomy is usually performed in connection with adductor tenotomy 1 cm of

Table 15 summarizes the measurements and shows that the overall Result of the 43 opera tions including 9 gracilis resections was a median of 1 per cent/year The difference be tween MIs of the raw data before and after the treatment is significant at the 1 per cent level P < 0 01

Operations with and without m. gracilis resection

The preceding analyses of obturatorius neurectomy and elongation of the hip flexors and hamstrings have shown only a doubtful and slight effect on the migration of the hips These Results could be due to the gracilis tendon often being resected at the same time For this reason an analysis was made of the part played by single operations in the total of Results

Author's investigation

The measurements were grouped into two classes depending on whether the gracilis muscle had been resected or not (Raw data on p 85 86 and 87)

Table 16 Results of anterior obturator neurectomy elongation of the hip flexors and proximal elongation of the hamstrings with and without m gracilis resection

GRACILIS RESECTION	n		AGE years OP	MIGRATION PERCENTAGE per cent PREOP	RESULTS per cent/year	P

P > 0 1

Table 14 summarizes the measurements and shows that the overall Result of the 22 oper tions including the 10 gracilis resections has been a median value of 0 per cent/year T difference between preoperative and postoperative MIs of the raw data is not significant > 0 1

Proximal elongation of the hamstrings

These operations were all performed as an elongation of the proximal origin of the muscle The tendons are released from the musculature which is transected proximally and tl tendons cut *intramuscularly about 7 cm distal to the ischial tuberosity Suture of tl* muscle bellies to the proximal tendon stumps gives a controlled elongation The result these operations was summarized by *Reimers* (1974)

Author's investigation

The material consists of all those patients with cerebral palsy who underwent proxima elongation of the hamstrings at the Orthopaedic Hospital Copenhagen from 1969 to 1971

The choice of patients was such that adductor operations had not been performed at th same time and that radiographs of the hip joint were available so that the course of the hi migration could be calculated for at least 6 months before and after the operation Th *selection reduced the material to 23 patients with a total of 43* operations including 9 *graci* lis resections (raw data on p 87)

Table 15 Result of proximal elongation of the hamstrings in 43 hip joints

n = 43	AGE years	OBSERVATION years		MIGRATION PERCENTAGE per cent			RESULT per cent/year

median	10^{11}	[illegible]	2^{2}	17	18	17	1
range	4^{5}-15^{4}	0^{6} 6^{4}	0^{11}-4^{8}	0 33	4 33	7 34	5 12

Discussion

After the positive results of the adductor operations on p 33 it might have been expected that the investigation would show a definite positive effect from the obturator neurectomies as this should produce a weakening of the adductors In spite of the small number of hips studied the operation appears to have a significant effect of in median value, 4 per cent/year

The lack of effect of the elongation of all the hip flexors was to be expected after the clinical experience with the hip joint in cerebral palsy and myelomeningocele The number of operations is not high but even an analysis of a larger number would hardly bring the Results obtained up to the level of those in the analysis of adductor operations in Chapter IV

A Result equal to 1 per cent/year after proximal elongation of the hamstrings is small even though there is a significant difference between the preoperative and postoperative values of the MIs However the median value for age is almost 11 years and as will be shown later, the Result following adductor operations depends on age and is greatest in children below the age of 4 years The same must hold for hamstring operations

Michelsson & Langenskiold's theory from 1972 which they supported by animal experiments that the hamstrings may provoke dislocation of the hip in infants in a frank breech presentation with extended knees and flexed hips is not contradicted by the slight improvement in the stability of the hips after elongation of the hamstrings as these children were all over 4 years of age and further it is only during treatment with exercises that the knees are extended while there is simultaneously flexion at the hips

If the explanation of the positive Result after operation on the hamstrings was that the children walked more and better after the operation it would be anticipated that elongation of the tendo Achilles had the same favourable effect on the hip joints On the contrary a significantly greater outwards migration of the femoral head was found after the operation than before The negative Result however is not of such a magnitude as to *contraindicate* elongation of the tendo Achilles The explanation may be that although the children walk more and better after the operation and thereby strengthen the muscles *that maintain the standing* position it is conceivable that they strengthen those muscles most that are already the best functioning (*Plum* 1975) The effect is accentuation of the existing *muscle imbalance* responsible for migration If this explanation is correct the analysis confirms the experience that it is not the poor extent of the ambulation that is significant for the development of the hip dislocation but the poor quality The positive Result after elongation of the hamstrings is therefore hardly due to the increase in ambulatory function

In single m gracilis resection the Result found was 2 *per cent/year* When the operation was combined with another type of intervention in the form of [illegible]

[illegible] gracilis operations

The lack of any Result from the operations without *m* gracilis resection at the same time in the case of children with a median *age of 11 years* suggests that the same operations at the age of 4 years will at most give a Result equal to that of gracilis resection at the same age

Author's investigation

The material originates from the Rigshospital s material of 1700 children, among whom a total of 21 single elongations were found which satisfied the conditions for preoperative and postoperative observation of the hip joints Elongation of the tendo Achilles is a very commonly employed operation, but it has often been carried out at such an early age that no preoperative radiographs are available (raw data on p 88)

Table 17 Result of tendo Achilles elongation in 21 hip joints

n = 21	AGE years	OBSERVATION years		MIGRATION PERCENTAGE per cent			RESULT per cent/year
	OP	PREOP	POSTOP	PRIM	PREOP	POSTOP

range	2^7-7^4	0^7-1^9	0^{10}-1^{11}	0-33	0 32	2-39	-21-6

P < 0 02

Table 17 summarizes the observations, and the Result is seen to be 4 per cent/year Examining the median values of the MP before and after operation the migration rate would appear to have been constant from 14 per cent to 15 per cent before operation and from 15 per cent to 16 per cent after operation However, the median value of the Results on the basis of the individual operations is negative, and the difference in MI from before to after operation is significant at the 2 per cent level, as P < 0 02

Chapter VI

Analysis of adductor operations

It was demonstrated in Chapter IV that by adductor myotenotomy possibly in combination with other soft tissue operations the MP in the subluxated »cerebral palsy« hip could be influenced to a considerable degree

Chapter V examined the Results of m gracilis resection obturator neurectomy elongation of the hip flexors or elongation of the hamstrings as single procedures and it was shown that at most these procedures influenced the migration slightly in the same positive direction as the combined adductor operations

Adductor intervention therefore appears to be the factor mainly responsible for the major results in the treatment and prophylaxis of the migrating hip

Having thus evaluated the Results following the individual soft tissue operations the adductor operations can now be analyzed more closely with regard of the influence of various factors on the Results

Author's investigation

The basis for the analysis of the adductor operations is the same patient material which was used to determine the effect and the result of the operations on the »cerebral palsy« hips in Chapter II In this and the following investigations the earliest available radiograph of the hips was not always the one used as the aim has been to have the preoperative observation and postoperative observation periods as equal as possible For the purpose of the analysis only hip joints were used where there has been a preoperative observation period with radiographs of at least 3 months (Raw data p 89 and 90)

The first adductor operation

Table 19 Result of the first adductor operation

n 39	AGE years	OBSERVATION years		MIGRATION PERCENTAGE per cent			RESULT per cent/year
	OP	PREOP	POSTOP	PRIM	PREOP	POSTOP	
median	4^3	0^9	1^5	33	43	33	15
range	1^1 18^0	0^3 7^3	0^8 2^0	0 86	14 100	8 69	31-100

P < 0 001

Table 19 summarizes the measurements showing that the Result of the first adductor operation was a median value of 15 per cent/year The improvement is significant P < 0 001

Before the operations the hips migrated outwards in median 7 per cent each year corresponding to a median MI of 7 per cent/year this being that value found on calculating from the MIs for the individual hips

Conclusion

The investigation of single operations in the form of resection of m gracilis elongation of *the hip flexors including the iliopsoas, rectus and sartorius, as well as proximal elongation of* the hamstrings has shown that elongation and weakening of these muscle groups gives a change in the yearly migration of at most 2 per cent by a median age of 4 years Compared to the spontaneous preoperative migration of about 10 per cent yearly, found on examination of subluxated »cerebral palsy« hips on p 31 in Chapter IV the muscle groups in question can at most be of minor importance for the hip migration

The positive Result of resection of the anterior branch of the obturator nerve supports the finding in Chapter IV, that the function of the adductor muscles are of great importance for the migration of the hip joint

The negative Result following elongation of the tendo Achilles supports the theory of muscle imbalance as the cause of the hip migration, since a quantitative increase in ambulation may accentuate the already existing imbalance if the use of the muscles around the hip is not improved qualitatively at the same time

Chapter VI

Analysis of adductor operations

It was demonstrated in Chapter IV that by adductor myotenotomy possibly in combination with other soft tissue operations the MP in the subluxated »cerebral palsy« hip could be influenced to a considerable degree

Chapter V examined the Results of m gracilis resection obturator neurectomy elongation of the hip flexors or elongation of the hamstrings as single procedures and it was shown that at most these procedures influenced the migration slightly in the same positive direction as the combined adductor operations

Adductor intervention therefore appears to be the factor mainly responsible for the major results in the treatment and prophylaxis of the migrating hip

Having thus evaluated the Results following the individual soft tissue operations the adductor operations can now be analyzed more closely with regard of the influence of various factors on the Results

Author's investigation

The basis for the analysis of the adductor operations is the same patient material which was used to determine the effect and the result of the operations on the »cerebral palsy« hips in Chapter II In this and the following investigations the earliest available radiograph of the hips was not always the one used as the aim has been to have the preoperative observation and postoperative observation periods as equal as possible For the purpose of the analysis only h p joints were used where there has been a preoperative observation period with radiographs of at least 3 months (Raw data p 89 and 90)

The first adductor operation

Table 19 Result of the first adductor operation

n 39	AGE years	OBSERVATION years		MIGRATION PERCENTAGE per cent			RESULT per cent/year
	OP	PREOP	POSTOP	PRIM	PREOP	POSTOP	
median	4^{3}	0^{9}	1^{5}	33	43	33	15
range	1^{1} 18^{8}	0^{3} 7^{3}	0^{8} 2^{9}	0 86	14 100	8 69	31 100

P < 0 001

Table 19 summarizes the measurements showing that the Result of the first adductor operation was a median value of 15 per cent/year The improvement is significant P < 0 001

Before the operations the hips migrated outwards in median 7 per cent each year corresponding to a median MI of 7 per cent/year this being that value found on calculating from the MIs for the individual hips

Conclusion

The investigation of single operations in the form of resection of m gracilis elongation of the hip flexors including the iliopsoas, rectus and sartorius as well as proximal elongation of the hamstrings, has shown that elongation and weakening of these muscle groups gives a change in the yearly migration of at most 2 per cent by a median age of 4 years Compared to the spontaneous preoperative migration of about 10 per cent yearly, found on examination of subluxated »cerebral palsy« hips on p 31 in Chapter IV, the muscle groups in question can at most be of minor importance for the hip migration

The positive Result of resection of the anterior branch of the obturator nerve supports the finding in Chapter IV that the function of the adductor muscles are of great importance for the migration of the hip joint

The negative Result following elongation of the tendo Achilles supports the theory of muscle imbalance as the cause of the hip migration since a quantitative increase in ambulation may accentuate the already existing imbalance if the use of the muscles around the hip is not improved qualitatively at the same time

Table 22 Unilateral adductor operation effect on the ipsilateral hip

n ~ 21	AGE years	OBSERVATION years		MIGRATION PERCENTAGE per cent			RESULT per cent/year
	OP	PREOP	POSTOP	PRIM	PREOP	POSTOP

range	3^{3}-12^{7}	0^{4}-3^{11}	0^{7}-2^{8}	4-63	9-63	18-56	-51-64

$0.02 < P < 0.05$

Table 20 shows the Results after one or more reoperations The median Result was [illegible] 5 per cent/year, which improvement was significant $0.02 < P < 0.05$

Before the secondary operation, the femoral head was stationary in relation to the acetabulum, as the median value of the preoperative MI was 0 per cent/year, when calculated from the MIs for the individual hips

Comparison of the first and the secondary adductor operations

Table 21 Comparison of the Results of first and secondary adductor operations

ADDUCTOR OPERATIONS	n	AGE years OP	MIGRATION PERCENTAGE per cent PREOP	RESULT per cent/year	P
FIRST	39	4^{3}	43	15	< [illegible] 001
SECONDARY	22	4^{11}	43	6 5	

Table 21 compares the most important data of the first and the secondary adductor operations

Age and preoperative MP are of the same magnitude but nevertheless the Result of reoperation [illegible] only less than half of that obtained from the first operation The difference between the Results of the operations is significant $P < 0.001$

Unilateral adductor operation

Of the total mat [illegible] and no oper[illegible] course, those 21 [illegible] The Result of operation was then calculated both for the ipsilateral [illegible] p 90) and for the contralateral hip (raw data on p 91)

tion that the result of soft tissue intervention around the hip joint is better in children under the age of 4 years (Raw data on p 89 and 90)

Table 27 Result of adductor operation, according to age

AGE	n	AGE years OP	MIGRATION PERCENTAGE per cent PREOP	RESULT per cent/year	P
< 4 years	23	2^{11}	43	16	= 0 012
> 4 years	38	6^{1}	40	8	

The Table shows that the Result following adductor operation was greater in children under the age of 4 years and the difference is significant, P = 0 012 In both groups the preoperative MP showed a median value of more than 40 per cent

Significance of the preoperative migration percentage

The material was then grouped according to the magnitude of the preoperative MP, as this likewise appears to have some significance for the Result (Raw data on p 89 and 90)

Table 28 Result of adductor operation according to preoperative migration percentage

PREOPERATIVE MIGRATION PERCENTAGE	n	AGE years OP	MIGRATION PERCENTAGE per cent PREOP	RESULT per cent/year	P
< 40 per cent	29	5^{11}	32	7	< 0 01
> 40 per cent	32	4^{2}	50	13	

The Table *shows that there is a significant difference in the Results* $P < 0\ 01$, the Result being better when the MP was more than 40 per cent Note that the median age is more than 4 years of age in each case

Significance of age and *preoperative* migration percentage in combination

The two preceding analyses show that both a low age and a high preoperative MP give best median Results The material has therefore been divided into four groups in order to compare the pairwise effect of the factors

The total adductor material was grouped according to the extent of the sequelae of the cerebral palsy Para diplegics are spastic in both legs and at most slightly in the arms Tetraplegics have also a function impeding spasticity in the arms (Raw data on p 89 and 90)

Table 24 summarizes the essential data There is no significant difference between the Results in the two groups P = 0 6

Significance of the intelligence

The adductor material is grouped according to the IQ A low IQ designates those children who at the time of operation were already under the Care of the Danish National Service for the Mentally Retarded or were expected to come under this The upper limit for low IQ has been put at about 75

Table 25 Result of adductor operation according to the relative IQ

IQ	n	AGE year OP	MIGRATION PERCENTAGE per cent PREOP	RESULT per cent/year	P
LOW IQ	35	4^7	44	9	= 0 3
NORMAL IQ	26	4^7	40	10 5	

The Table summarizes the most important data There is no significant difference between the Results of the operations in the two groups P = 0 3

Significance of sex

The material is grouped according to boys and girls (Raw data on p 89 and 90)

Table 26 Result of adductor operation according to sex

SEX	n	AGE years OP	MIGRATION PERCENTAGE per cent PREOP	RESULT per cent/year	P
GIRLS	28	5^4	42	9	= 0 8
BOYS	33	4^3	41	11	

The Table shows that the difference between the Results in the two groups is not significant P = 0 8

Significance of age

The material is grouped *according to age* as there were indications earlier in the investiga

tion that the result of soft tissue intervention around the hip joint is better in children under the age of 4 years (Raw data on p [illegible] and 90)

Table 27 Result of adductor operation, according to age

AGE	n	AGE years OP	MIGRATION PERCENTAGE per cent PREOP	RESULT per cent/year	P
< 4 years	23	2^{11}	45	16	= 0 012
> 4 years	38	6^{1}	40	8	

The Table sh[illegible]
the [illegible]
tiv[illegible]

Significance of the preoperative migration percentage

The material was then grouped according to the magnitude of the preoperative MP, as this likewise appears to have some significance for the Result (Raw data on p [illegible] and 90)

Table 28 Result of adductor operation according to preoperative migration percentage

PREOPERATIVE MIGRATION PERCENTAGE	n	AGE years OP	MIGRATION PERCENTAGE per cent PREOP	RESULT per cent/year	P
< 40 per cent	29	5^{11}	32	7	< 0 01
> 40 per cent	32	4^{2}	50	15	

The Table shows that there is a significant difference in the Results P < [illegible] 01, the Result being better when the MP was more than 40 per cent Note that the median age is more than 4 years of age in each case

Significance of age and preoperative migration percentage in combination

The two preceding analyses show that both a low age and a high preoperative MP give best median Results The material has therefore been divided into four groups in order to compare the pairwise effect of the factors

Table 29 Result of adductor operation according to age and preoperative migration *percentage*

AGE AT OP	MIGRATION PERCENTAGE PREOP	
	⩽ 40 per cent	> 40 per cent
⩽ 4 years	*n* = 9 10 per cent/year	*n* = 14 21 per cent/year
> 4 years	n = 20 5 5 per cent/year	n = 18 10 per cent/year

Table 29 shows the Result of the adductor operations grouped according to age and pre operative MP There is a significant difference between the Result for preoperative MP less than and more than 40 per cent and the child under 4 years of age as well as between the Results for age less than and more than 4 years of age and the MP more than 40 per cent

The best Result was found when the child was under the age of 4 years and the hip had migrated at least 40 per cent Conversely the Result was least good when the patient was over 4 years of age and the hip had migrated less than 40 per cent

Discussion

The analysis of the first adductor operation shows that the Result was 15 per cent/year This confirms the result of the pilot investigation in Chapter IV

The Result of the adductor operations is of quite another order of magnitude to that of the other operations except anterior obturator neurectomy examined in Chapter V In what follows therefore no account has been taken of the accompanying soft tissue opera tions

An analysis of the individual measuring data shows that the median value of the pre operative spontaneous MI was 7 per cent/year while the pilot investigation showed a migra tion about 10 per cent each year

An examination of the secondary adductor operations shows that the median Result was 6 5 per cent/year This means that since after the earlier operations on the adductors no certain migration was found the secondary operations must have resulted in an improve ment

The finding that the Result of the secondary *operations is less than those of the first* operations suggests that what is of greatest significance for the stability of the hips is an im balance between hip abductors and adductors If a better function of the hip abductors was not achieved following the first operation *this possibility* is no doubt present following the secondary operations but to a significantly smaller degree than after the first operation

Samilson et al (1967) warned against unilateral adductor myotomies in cerebral palsy be cause of the risk of abduction *deformity* of the operated *hip and adduction contracture* and

subluxation of the unoperated hip *Baacke & Tonnis* (1974) and *Bjerkreim* (1974b) showed how a hip which is loaded in abduction results in secondary dysplasia and possibly osteo arthrosis in the contralateral hip which becomes adducted In view of these findings the unilateral adductor operations have been analyzed using both the first operation and se condary operations with a known preoperative and postoperative course

Comparing the effect on the hips operated on unilaterally in Table 22 with the effect on the contralateral unoperated hips in Table 23 it is seen that in spite of both first operation and secondary operations the Result in these unilateral operations was of the same magni tude as the Result in the case of the first bilateral operation but it seems that the operation exerting a negative influence on the unoperated hip the non significant median value of the Results for these being 4 per cent/year

Anyone with experience in such operations however knows of cases where a unilateral adductor tenomyotomy involves a risk of dislocation in the contralateral hip This was the case with patient No 25 for example with spastic tetraplegia and unilateral dislocation of the hip After the hip was reduced by means of adductor tenomyotomy the outwards migration of the contralateral hip was accelerated The control was stopped and three years after the first operation this hip was found dislocated (This was after the end of the period of observation) Among other forms of intervention an osteotomy of the femur was performed to reduce the hip

If the hypothesis is correct that the hip is affected by the function of the surrounding muscu lature no difference should be anticipated in the radiological Results of operation on account of differences in the type of spasticity diagnosed IQ or sex provided the preopera tive MP and age are the same Even though these prerequisites could not be fulfilled com pletely the investigation shows that in fact no differences in Results were found as postu lated

Previously attempts to treat deformities in the hips in cerebral palsy were advised against if the patient was neurologically and intellectually immature *Samilson et al* showed in 1972 that it can pay to provide treatment for the hip in this group of patients as well with a view to preventing subsequent complications craving nursing care such as pain scoliosis fractures and decubitus The present study confirms that the Result of adductor operations measured by the stability of the hip before and after operation is independent of the extent of the neurological lesions and of the IQ It has been shown in a corresponding manner (*Rei mers* 1974) that the result of operation for contracture of the hamstrings in children with cerebral palsy is also independent of the IQ

The analysis of age and preoperative MP shows that both these factors are of significance for the Result of the adductor operations without it being possible to decide whether an age less than 4 years or a preoperative MP of more than 40 per cent is the more important factor

Samilson et al in 1967 found that the best hip stability after soft tissue operations was ob tained in children under 12 years of age The present investigation does not exclude the pos sibility that in isolated cases good results can also be obtained in older patients

Example

Patient No 20 a boy with spastic d plegia and mental retardation Examination at the age of 17 years showed no ambulatory function but good control of the head The sitting pos tion was poor because of adduction of the right hip and a cons derable clin cal scol osis There was contracture of the hip ad ductors and flexors as well as of the hamstrings with organic l mitation of extension in the knees A rad ograph of the h p jo nts showed a MP of 55 per cent in the right hip and of 24 per cent in the left hip There was no pain and as the pat ent was 17 years of age it was not considered that his cond tion

would become exacerbated so operation was abstained from

A year later there was pain in the right hip, the scoliosis had progressed, the sitting position was poorer, and [illegible]

only moderate and did not impede function The general condition of the patient was more satisfactory, and it was easier to provide nursing care Fig 12 shows the Result of the operation on the migration of the hips

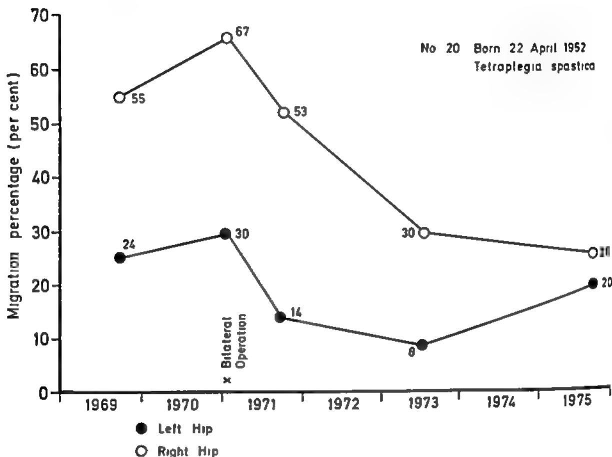

Figure 12
Visualization of the result of adductor operation at the age of 18 years

The great significance of age and preoperative MP for the outcome of adductor operations makes it necessary to revise our evaluation of the Results following gracilis and obturator neurectomy, as well as elongation of the hip flexors or the hamstrings, as the influence of the two factors mentioned on these operations has presumably the same significance as in the case of the adductor operations

Table 18 shows that the Result of the anterior obturator neurectomy alone was 4 per cent/year with a median age of 8 years and a preoperative MP of 21 5 per cent Comparing this Result with that in Table 29, it is seen that the Result of adductor operation in children more than 4 years of age (median 6[10] years) and with a preoperative MP of less than or equal to 40 per cent (median 35 per cent), was of the same order of magnitude, namely 5 5 per cent/year This suggests that the Result of the obturator neurectomy is a real one as might have been expected

The Result of the elongation of the hamstrings was only 1 per cent/year, with a high age and low preoperative MP, so that further investigations are necessary, for example following operations preferably on younger patients, before it can be established that the hamstrings are of significance for the quality of the hip joint

Table 18 shows that the Result of the gracilis resection alone was [illegible] per cent/year with a median age of 4 years and a preoperative MP of 21 per cent The Result of the resections is not statistically significant This problem however, might be clarified in the following manner

The gracilis muscle functions as a hip adductor when the knee is held in the extended position and in the standing position it thus contributes to crossing the legs In the sitting position the knee is bent, and as a result the m gracilis is relaxed and can therefore not affect the hip directly If at the same time there are contractures in the m gracilis and in the tensor fascia lata or in the other hip abductors the child will often lie spontaneously in the »frog position« but this position corresponds to the »Lorenz I position« which was employed before Salter s »human position« (*Salter et al* 1969) to improve the position of the femoral head in the acetabulum in congenital dislocation of the hip From static and dynamic considerations therefore the m gracilis would not be expected to influence the hip unfavourably when the child is sitting or lying with bent knees However, the Result of these operations which in spite of all was positive if not significant can also be explained by the fact that after the operation the hip joints have been kept in abduction for 3 weeks often followed by an abduction night splintage with the result that the other hip adductors have come under tension and perhaps elongated as a result

To investigate further the significance of the m gracilis for the hip joint one could examine whether there is a relationship between the abduction of the hip with the m gracilis stretched and relaxed and the simultaneous MP of the same hip

Conclusion

The analysis of adductor operations in »cerebral palsy« hips has shown a significant improvement in the relation to the femoral head to the acetabulum

The first adductor operation gives a significantly better Result than the secondary interventions Measured by the MIs the Result of the reoperations is only less than half of the first operation in spite of equality of age and preoperative MP

On analyzing all adductor operations with a known preoperative and postoperat[illegible]

[illegible] of that Result obtained on the ipsilateral side

The extent of the cerebral lesion expressed by the diagnosis para diplegia or tetraplegia is not found to have any essential or significant effect This suggest that the hip joint is only influenced by the function of the peripheral surrounding structures and is unaffected by the cerebral neurolesion

Differences in IQ and sex have likewise no significance for the Result

On the other hand there is a significantly greater improvement in the stability of the hip in children under 4 years of age and in hips with a preoperative MP of more than 40 per cent without it being possible to find any significant difference in the weight of these two factors

As was concluded in Chapter IV however one should not wait until the MP [illegible] cent to get a greater [illegible] ment should be in [illegible]

if the best radiological Result is to be obtained on the long term view This requires evaluation of the stability of the hip on a radiograph as soon as the diagnosis of cerebral palsy is suspected

Comparing the Results of anterior obturator neurectomy with the adductor operations with nearly the same age and preoperative MP it is clear that the Results are of the same magnitude

Elongation of the hip flexors did not provide a better stability of the hip joints on the other hand it is not possible to exclude that operations on the hamstrings or m gracilis might have an importance for the migration of the hip joint

Chapter VII

Relation between migration percentage and abduction of the hip

Among other results in the previous pages it was shown that a femoral head which migrates outwards spontaneously can after elongation and at the same time weakening of the adductor muscles be brought to migrate inwards under the acetabulum in relation to Perkins line This result of the operation must be due to a termination of the influence of the deforming force The deforming force may therefore be the contracture which was removed by the operation on the adductors or it may lie in a too powerful functioning of the adductor muscles *in relation to the antagonists the hip abductors*

It should be possible to determine which factor is the more important by examining the correlation between the hip abduction and the MP A high correlation must signify that abduction is of great importance for the stability of the hip and conversely a low correlation that abduction is of slight significance

Adductor operations are often combined with a gracilis resection so in order to distinguish if possible between the isolated gracilis effect on the stability of the hip and the effect of the other adductors the investigation should be done with the legs both flexed and extended

Author's investigation

The material consists of 95 children with cerebral palsy examined at the Rigshospital and in the Outpatient Clinics of Ebberødgård and the Children s Hospital Vangede (Subnormality Institutes) All the children had undergone the first adductor operation after 1st January 1969 at the Orthopaedic Hospital Copenhagen or after the 1st April 1973 at Orthopaedic Department U the Rigshospital The evaluation of the MP was based on the latest clinical and radiographic examination before the operation All examinations were made by the author

Examination of the hip abduction is done with the patient supine on a firm support (*Holt* 1965) Both hips are abducted at the same time first with 90° flexion in the hips and knees then as far as possible with completely extended hip and knee joints Any difference in abduction between the two sides is easily revealed when the supporting surface is firm The abduction is performed slowly and without exerting force It is a well known fact that physiotherapists for example can gradually obtain a greater abduction during treatment than can be got on clinical examination The rapid abduction that reveals the spastic contracture is not of interest in this connection The magnitude of the abduction is evaluated and checked by means of a goniometer As a rule the radiographs are not examined until after the clinical examination

if the best radiological Result is to be obtained on the long term view This requires evaluation of the stability of the hip on a radiograph as soon as the diagnosis of cerebral palsy is suspected

Comparing the Results of anterior obturator neurectomy with the adductor operations with nearly the same age and preoperative MP, it is clear that the Results are of the same magnitude

Elongation of the hip flexors did not provide a better stability of the hip joints, on the other hand it is not possible to exclude that operations on the hamstrings or m gracilis might have an importance for the migration of the hip joint

Cozen (1968) *Baacke & Tonnis* (1974) and *Bjerkreim* (1974b) have reported cases in which dysplasia has developed in adducted hips where the adduction was due to an abduction in the contralateral hip either the result of an arthrodesis or an uncorrected shortening of the lower extremity

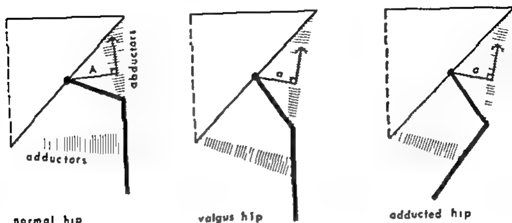

Figure 13
Demonstration of the reduced effect of the abductors in a valgus or adducted hip due to shortening of the »lever« A

Figure 13 shows that an adducted hip just as in the case of a valgus deformity causes the hip abductors to function inefficiently since the distance from the centre of movement in the head of the femur to the functional axis of the abductors becomes less than that in the normal hip When the »lever« becomes shorter the moment decreases correspondingly (*Merchant* 1965) This signifies that a temporary faulty position in which the hips are ad ducted for a period for example in coxitis and Calve Legg Perthes disease could trigger off a self aggravating muscle imbalance

The investigation shows that the correlation between the MP and the hip abduction is poor This must signify that it is not the absolute magnitude of the abduction (= the degree of brevity of the adductors) that bears the primary significance for the hip deformation but the relative imbalance between the hip adductors and abductors that is the deforming force

Example
Patient No 33 a boy with spastic and athetoid tetraplegia At the age of 6 years he underwent opera tion on the left adductors and both mm gracilis Six months before operation the MP in the right hip was 13 per cent in the left hip 50 per cent Six months after the operation the MP was 13 per cent and 23 percent respectively Before operation the corresponding hip abduction with leg flexed was 60° in the right hip and 50° in the left hip After operation the abduction was 60° and 70° respectively

Figure 14 shows an example of a hip with considerable subluxation but where there was hardly any brevity of the adductors and where the subluxation disappeared after operation on the adductors

Table 30 Relation between migration percentage and passive abduction of the hip

MIGRATION PERCENTAGE *per cent*	n	PASSIVE ABDUCTION OF ONE HIP degrees			
		FLEXED LEGS		STRAIGHT LEGS	
		median	range	median	range
MP = 0	20	45	30-90	20	15-50
0 < MP ⩽ 33	114	45	10 85	25	0 60
33 < MP ⩽ 66	*44*	*40*	5-65	*20*	5-60
66 < MP ⩽ 100	11	25	0 50	15	-5 25
MP ⩾ 0	*189*	r = 0 35 P < 0 001		r = -0 31 P < 0 001	

Table 30 summarizes the measurements (Tables on p 91) and shows there is a negative correlation between a MP ⩾ 0 per cent and passive hip abduction with flexed and extended legs as r = 0 3 (r is significantly different from 0 P < 0 001) This means that there is only a slight chance of deducing from the degree of hip abduction to the corresponding MP with reasonable certainty and *conversely In the individual groups of MPs the range of abduc*tion is seen to be very wide

Discussion

An examination of the literature failed to show any experimental studies that can explain the clinical observation that contractures in muscles and tendons develop in the better func*tioning of* two antagonistic muscle groups in growing subjects Contracture in the adductors is seen for example in children (and dogs *Whittick* 1974) with subluxation of the hip in cases of Calve Legg Perthes disease (but must not be confused here with the initial »defense« in the adductor muscles) in subluxated hips in patients with myelomeningocele and in children with cerebral palsy As the contracture can develop independently of spasticity the possibility that this might be the causal factor may be ignored This does not deny the experience that the spasticity in cerebral palsy is usually *most pronounced in the most* powerfully functioning muscle groups and as a result may accentuate a muscular imbalance

The most probable relation appears to be that muscles and tendons only grow in length when they are stretched by a sufficient force which must originate from the antagonist When the antagonist is too week to influence the agonist the latter remains too short in relation to the child s growth (*Sharrard* 1967) As the weaker antagonist is stimulated too much it becomes *too long and functions even more ineffectively* The imbalance hereby be*comes self aggravated* (*Sharrard* 1975a) A brevity of the adductors must therefore signify that the adductors function better than the abductors but does not exclude the possibility that both muscle groups may be weak There must *therefore be some degree of correlation between the magnitude of the abduction and the MP* of the hip This is in fact demonstrated by the investigation as r differs significantly from *0*

Conclusion

It is probably correct to conclude that muscles and tendons only grow in length when extended by an adequate force. On the basis of this conclusion, a brevity of the adductors must imply that these function better than the antagonists = the abductors, an imbalance which is self amplifying. In a corresponding manner, the investigation shows that there is a correlation between the abduction and the MP in a »cerebral palsy« hip, as r differs significantly from 0.

However, the correlation is only slight, as r = 0.3. This implies that it cannot be the brevity in itself that is the primary influence responsible for the outwards migration of the hip. The preceding investigations have shown that elongation and weakening of the adductors of the hip exert a positive effect, so that it must be the imbalance between the adductors and the more weakly functioning abductors that constitutes the deforming force.

The correlation is least when the abduction is measured with extended hips and knees. As shown in the previous investigations, this suggests that the gracilis muscle has only a slight significance as a deforming force. In a corresponding manner, the abduction must tell us more about the stability of the hip when measured with 90° flexion in hip and knee.

The most important results are that if the abduction is reduced to less than 30°, the femoral head as seen on a radiograph must have migrated beyond the rim of the acetabulum, and that an investigation of the abduction cannot replace a radiograph of the hip, as even a subluxated hip may show abduction up to 60°.

½ year before operation
Migration Percentage 50 per cent

½ year after operation
Migration Percentage 23 per cent

Figure 14
Effect of adductor operation on a hip joint with hardly any brevity of the adductors

Sharrard et al found in 1975 in their analysis of patients with limited abduction in the hip measured during extension of hip and knee joint that the greater the instability present in the hip before operation on the adductors the greater the limitation of abduction How ever no correlation was found between abduction and stability of the hip after the opera tion They therefore concluded that full range of abduction was probably not the most im portant factor in obtaining better hip stability Of greater significance was the finding that a balance between abductors and adductors and between flexors and extensors corre sponded better with the maintenance of hip stability In other words the conclusion reached by *Sharrard et al* is the same as in the present study apart from the fact that they involved the flexors and extensors

Leffman in 1959 found that the degree of limited abduction in subluxation did not corre spond to the changes on the radiographic picture and conversely

The correlation with the MP is poorer when the abduction is measured with the legs ex tended and this also tells against the m gracilis playing any real part in the hip deformity It would therefore seem more correct to measure hip abduction with 90° flexion in hip and knee

According to Table 30 the investigation shows that if a »cerebral palsy« hip can be ab ducted more than 50° the hip is not dislocated and if the abduction is reduced to less than 30° the femoral head does extend beyond the acetabular rim An abduction study cannot replace a radiograph of the hips as a hip which is subluxated may nevertheless have a range of abduction up to 60°

and this makes the use of the MI more complicated The more likely explanation of the greater effect is that muscle imbalance is more pronounced in the poorer hips so that a change in balance obtained by an adductor operation will give a greater Result

The observation that there is no systematic regularity between hip abduction and MP shows once again that a radiographic investigation is necessary if the stability of the hip is to be evaluated

It is known that when oestrogens are given to dogs late in pregnancy or to whelps early after birth this produces laxity in the joint capsule of the hip, which may lead to dysplasia or osteoarthrosis (*Gustavson* 1971 and *Whittick* 1974) Most investigators today also regard laxity as the most important factor disposing to congenital dislocation or subluxation in children presenting in the head position at birth (*McKibbin* 1970) *Fredensborg* (1976) found correspondingly that in children who had been treated early for dislocation of the hip the joints were significantly more lax at the age of 10 years than in a corresponding control group

This instability can itself trigger off a muscle imbalance as the effect of the hip abductors is weakened when the femoral head can slide in relation to the acetabulum The restricted hip abduction which can be demonstrated later which is also present when the hip is reduced (*Hart* 1952 *Salter* 1967 *Tanabe et al* 1972 and *Bjerkreim* 1974a) can be regarded as expressing an imbalance between abductors and adductors as found to a more pronounced degree in cerebral palsy *Whittick* (1974) and *Riser* (1974) both found corre

these muscles

We know from many investigations that an unstable hip in infancy and childhood is followed by osteoarthrosis in the adult and *Weickert* in 1975 estimated that 10 to 20 per cent of all newborn infants had hip changes varying from dysplasia to dislocation

However so long as we have not examined the question whether a not completely »optimal« hip with a MP of 10 per cent for example at the age of 1 year, will result in osteoarthrosis of the hip later on the correct scientific background is not present for too rigoristic claims as to what is the »normal« hip in the childhood

In myelomeningocele the level of the neural deficit remains the most important determinant of the ability to walk (*DeSouza & Carroll* 1976) A level pelvis and free motion of the hips appear to be more important for the function than reduction of the hips (*Feiwell et al* 1978)

But if we aim at containment at the hips in a patient with myelomeningocele the primary intervention must be to treat the muscle imbalance between the abductors and adductors

General conclusion

1 On the basis of the literature it is shown that the relation of the femoral head to the acetabulum on a radiograph may best be described by means of a *Migration Percentage (MP)* by measuring the percentage of the head projecting outside Perkins line (= the acetabular edge)

Chapter VIII

General discussion

As the preceding analyses were carried out on children operated on for the sequelae of cere bral palsy the aim of the present study might have been to elucidate the various problems presented by the hip joints in these children It was tempting however to use the oppor tunity to show that the motto on the first page of the study also applies to the hip joint and the surrounding muscles under other circumstances than those of cerebral palsy alone so the scope of the hypothesis was enlarged to hold for all child hips

The most important criticism against such a generalization might well be that in con *genital dislocation* of the hip the muscles show no spasticity But if by spasticity is under stood that the muscles counteract a rapid stretch by reflex action then in that disease of the hip spastic shortening of the adductors are also often found clinically

As remarked in the introduction the bones and joints do not appear to be interested in whether a muscle imbalance is neurogenic or myogenic and as anticipated the results of adductor operations did not differ significantly between para or diplegics and tetraplegics just as there were no differences with regard to intelligence and sex

As to the »cerebral palsy« hip the study has shown that muscle imbalance between more weakly functioning abductors and adductors causes the hip to migrate outwards in the years *of infancy and childhood As a result some hips will dislocate any ambulatory* capacity present will be lost and the children will have to undergo the period of pain often followed by severe subluxation and dislocation in cerebral palsy (*Samilson et al* 1972 and *Sharrard et al* 1975)

The study shows that the Results are best following the first operation on the adductors However the Results of any possible secondary operation are not *so poor that such opera* tions should be omitted altogether but occasionally when the abductors are very weak a *varus osteotomy of the femur should be included as an alternative* in the considerations

Nor should a unilateral adductor operation be omitted if it is necessary to create a balance at the hip pelvis or spinal column On the other hand elongation of the hip flexors m gracilis or hamstrings should not be performed for the sole purpose of improving hip stability

The unexpected reverse Result following an operation to improve gait such as elongation of the tendo Achilles is merely a further indication that vertical loading of the hip in itself *has no positive effect on the hip* stability

The observation that the Result of adductor operation is greatest in children under the age of 4 years can be explained by the more rapid regeneration of the acetabulum and sur roundings the younger the child

The greater effect obtained in the case of a *large preoperative MP might* be due to a built in fault in the calculation of the Results of the MIs as no distinction has been made as to whether an improvement of say 10 per cent/year is from a MP of 60 per cent to 50 per cent or from 30 per cent to 20 per cent However by taking the ratio of the MI to the mean value between preoperative and postoperative MP the Results are not altered essentially

and this makes the use of the MI more complicated The more likely explanation of the greater effect is that muscle imbalance is more pronounced in the poorer hips so that a change in balance obtained by an adductor operation will give a greater Result

The observation that there is no systematic regularity between hip abduction and MP shows once again that a radiographic investigation is necessary if the stability of the hip is to be evaluated

It is known that when oestrogens are given to dogs late in pregnancy or to whelps early after birth this produces laxity in the joint capsule of the hip which may lead to dysplasia or osteoarthrosis (*Gustavson* 1971 and *Whittick* 1974) Most investigators today also regard laxity as the most important factor disposing to congenital dislocation or subluxation in children presenting in the head position at birth (*McKibbin* 1970) *Fredensborg* (1976) found correspondingly that in children who had been treated early for dislocation of the hip the joints were significantly more lax at the age of 10 years than in a corresponding control group

This instability can itself trigger off a muscle imbalance as the effect of the hip abductors is weakened when the femoral head can slide in relation to the acetabulum The restricted hip abduction which can be demonstrated later which is also present when the hip is reduced (*Hart* 1952 *Salter* 1967 *Tanabe et al* 1972 and *Bjerkreim* 1974a) can be regarded as expressing an imbalance between abductors and adductors as found to a more pronounced degree in cerebral palsy *Whittick* (1974) and *Riser* (1974) both found correspondingly that the muscle mass of the abductors is reduced in dysplasia of the hip in dogs

As a consequence of this knowledge instability of the hip joint in the childhood might be treated with an elongation and weakening of the adductors in the presence of brevity of these muscles

We know from many investigations that an unstable hip in infancy and childhood is followed by osteoarthrosis in the adult and *Weickert* in 1975 estimated that 10 to 20 per cent of all newborn infants had hip changes varying from dysplasia to dislocation

However so long as we have not examined the question whether a not completely »optimal« hip with a MP of 10 per cent for example at the age of 1 year will result in osteoarthrosis of the hip later on the correct scientific background is not present for too rigoristic claims as to what is the »normal« hip in the childhood

In myelomeningocele the level of the neural deficit remains the most importan de[illegible] nant of [illegible]
hips a [illegible]
1978)

But if we aim at conta nment at the hips in a patient with myelomeningocele the primary intervention must be to treat the muscle imbalance between the abductors and adductors

General conclusion

1 On the basis of the literature it is shown that the relation of the femoral head to the acetabulum on a radiograph may best be described by means of a *Migration Percentage (MP)* by measuring the percentage of the head projecting outside Perkins line (= the acetabular edge)

2 The difference between the MP measured in neutral rotation and in internal rotation of

the femur is shown to be so small that it does not justify an examination in both rotations when carrying out a radiographic investigation of the stability of the hip

3 *For a hip to be »optimal« in children under the age of 4 years* it is shown that the femoral head should not reach further than Perkins line Between the ages of 4 and 16 years at most 5 per cent of the visible part of the femoral head is beyond this line This concept of the »optimal« hip is only used provisionally

4 *It is shown that a CE angle < 20° in a child over the age of 4 years* indicates that the hip is not »optimal« whereas a CE angle ≥ 20° tells us nothing certain as to the stability of the hip

5 It is shown that the rate of migration in a »normal« child hip is less than 1 per cent per annum

6 It is shown that the subluxated hip in cerebral palsy is aquired and that in such hips the spontaneous migration is a median value of about 10 per cent per annum

7 The first tenomyotomy of spastic hip adductors in cerebral palsy is shown to result in 57 per cent of the hips retaining or improving their stability in the short run

8 It is shown that during an observation period of 6½ years following possibly several soft tissue operations at the hip the stability is retained or improved in about 33 per cent of the hips on the basis of a comparison with the primary radiographic investigation and is im proved in about 70 per cent of the hips in relation to the maximum MP experienced by the hip during the period of observation

9 *It is shown that operation should be carried out on the »cerebral palsy« hip without allow* ing a period of observation to elapse; as soon as a subluxation is noted in order to achieve the best possible final result as evaluated by the radiograph For this reason the MP should be evaluated from a radiograph of the hips as soon as the diagnosis is suspected

10 It is shown that resection of r anterior n obturatorius gives an improvement in the hip stability of the same magnitude as the adductor operation

11 In this analysis there has been no effect of elongation of the hip flexors including the mm iliopsoas rectus and sartorius on the hip stability and no significant Result of the m gracilis resection could be shown However it is not possible to exclude some effect of the proximal elongation of the hamstrings

12 The stability of the hip is shown to become poorer following elongation of the tendo Achilles *This suggests that a quantitative increase in the ambulatory capacity may accen* tuate an existing muscle imbalance when the gait is not improved qualitatively

13 It is shown that improvement after operations subsequent to the first adductor opera tions is only less than half of that obtained in the first operation

14 It is shown that adductor operation on one hip does affect the contralateral hip with a *reverse* Result about one third of the Result obtained on the ipsilateral side

15 Differentiation between para or diplegia and tetraplegia or between sex and IQ is not shown to have any significant effect on the Result of adductor operations as evaluated by an investigation of the radiograph of the hip

16 Following adductor operations there is shown to be a significantly greater improvement in the stability of the hip in spastic children under the age of 4 years compared to those over the age of 4 years and the Result is shown to be greatest with a preoperative MP more than 40 per cent These two factors appear to carry same weight

17 It is shown that there is only a slight correlation between the degree of abduction in an [illegible]

18 It has been shown with the aid of the »cerebral palsy« hip that the head of the femur can be made to migrate inwards in relation to the acetabulum following an adductor operation and it has been shown in addition that the interventions which often accompany the operation such as lengthening of the m gracilis hip flexors and hamstrings result at the most in a minor effect This must signify that it is either the lengthening or the resulting weakening of the adductors that has the greater significance for the improvement in hip stability As it has thus been demonstrated that anterior obturator neurectomy has an effect similar to that obtained by tenomyotomy of the adductors and that there is only a slight relation between the magnitude of the brevity of the adductors and the stability of the hip it may be concluded that our original hypothesis is correct That is that in the growing child there is a connection between the position of the head of the femur in relation to the acetabulum and the function of the surrounding muscles In addition the investigation has shown that it is especially the balance between the hip adductors and abductors that has significance for the hip stability in the frontal plane as weak abductors in contrast to better functioning adductors result in the femoral head migrating outwards in relation to the acetabulum

the femur is shown to be so small that it does not justify an examination in both rotations when carrying out a radiographic investigation of the stability of the hip

3 For a hip to be »optimal« in children under the age of 4 years it is shown that the femoral head should not reach further than Perkins line *Between the ages of 4 and 16 years* at most 5 per cent of the visible part of the femoral head is beyond this line This concept of the »optimal« hip is only used provisionally

4 It is shown that a CE angle < 20° in a child over the age of 4 years indicates that the hip is not »optimal« whereas a CE angle ⩾ 20° tells us nothing certain as to the stability of the hip

5 It is shown that *the rate of migration in a »normal« child hip is less than 1 per cent per* annum

6 It is shown that the subluxated hip in cerebral palsy is aquired and that in such hips the spontaneous migration is a median value of about 10 per cent per annum

7 The first tenomyotomy of spastic hip adductors in cerebral palsy is shown to result in 57 per cent of the hips retaining or improving their stability in the short run

8 It is shown that during an observation period of 6½ years following possibly several soft tissue operations at the hip the stability is retained or improved in about 33 per cent of the hips on the basis of a comparison with the primary radiographic investigation and is improved in about 70 per cent of the hips in relation to the maximum MP experienced by the hip during the period of observation

9 It is shown that operation should be carried out on the »cerebral palsy« hip without allowing *a period of observation to elapse as soon as a subluxation is noted in order to achieve* the best possible final result as evaluated by the radiograph For this reason the MP should be evaluated from a radiograph of the hips as soon as the diagnosis is suspected

10 It is shown that resection of r anterior n obturatorius gives an improvement in the hip stability of the same magnitude as the adductor operation

11 In this analysis there has been no effect of elongation of the hip flexors including the *mm iliopsoas rectus and sartorius on the hip stability* and no significant Result of the m gracilis resection could be shown However it is not possible to exclude some effect of the proximal elongation of the hamstrings

12 The stability of the hip is shown to become poorer following elongation of the tendo Achilles This suggests that a quantitative increase in the ambulatory capacity may accentuate an existing muscle imbalance when the gait is not improved qualitatively

13 It is shown that improvement after operations subsequent to the first adductor operations is only less than half of that obtained in the first operation

14 It is shown that *adductor operation* on one hip does affect the contralateral hip with a reverse Result about one third of the Result obtained on the ipsilateral side

be used As the correlation coefficient between MP and CE angle is only 0 76 a new »normal material« of MPs was prepared based on measurements of the hip joint on a larger number of urographs From this material patients were excluded with Wilms tumour and neuromuscular diseases as well as children with infections of the urinary tract in the first year of life and only films of the hip in neutral abduction adduction were used As the starting material consists of children with suspected or manifest urological disease the material in spite of selection must be biased by hips which are not »optimal« (Table 3)

In children under the age of 4 years the observation that in 102 out of 108 hip joints the femoral head is completely covered by the acetabulum indicates that Perkins line represents the maximum lateral position for the femoral head in the »optimal« hip In children between the ages of 4 and 16 years at most 5 per cent of the visible part of the femoral head is lateral to Perkins line in the »optimal« hip thus being the finding in 159 out of 247 hips i e not quite ⅔ This concept is only a provisional one i e until we know more about the relation between the MP and coxarthrosis

A comparison between measurements of the same hip joints using CE angles and MPs (Table 4) gives as result that a CE angle < 20° indicates that the hip in a child above the age of 4 years is not »optimal« On the other hand it is not possible with certainty to reach any conclusion as to the stability of the hip in childhood when the CE angle is ≥ 20° In accordance with that uncertainty the correlation between the CE angles ≥ 20° and the MPs is only 0 282

The following terms are then defined *Migration Percentage (MP)* the fraction (expressed in per cent) of the visible part of the femoral head which on an a p radiograph has migrated beyond Perkins line (= acetabular rim) The measurements are made along a line horizontal to the pelvis *Migration* the difference between two instantaneous MPs determined at two different times *Subluxation* the MP is at least 33 per cent *Dislocation* the MP is 100 per cent *Dysplasia* the term is used during the period before the femoral head has become visible on a radiograph and signifying that the acetabulum is sloping with a retreating border as if it had been squeezed during growth

A method is then described of recording the course of the migration in a coordinate system with MP against time (Fig 5)

In order to visualize those changes in the MP of the hips resulting from treatment a coordinate system may be used with the same units in both coordinates (Fig 6)

Chapter IV Table 3 shows the spontaneous migration of the »normal« hip which is less than 1 per cent per annum The Table also shows that the »normal« hip does not subluxate

Out of a total of 441 patients with cerebral palsy admitted to the Orthopaedic Hospital in Copenhagen during the period January 1st 1968 to July 1st 1971 those 38 children under the age of 19 years are selected who had a subluxation of the hip during that period and who for that reason underwent an operation on the adductors possibly combined with other soft tissue operations but not at the same time with elongation of the hamstrings or osteotomy of the femur

In 39 cases the number of radiographs are adequate to determine the migration of the hips before and after the first adductor operation An — —
the subluxation was most often acquired (Fig 7 as
operation most of the hips migrated inwards agai

Sharrard et al found in 1975 that after the first adductor operation stability was improved or maintained in 75 per cent of the hips Their investigation is confirmed by an analysis of the above 39 hips together with 18 hips without preoperative observation (Fig 9 and Table 6) with a result of 57 per cent The investigation also shows that if treatment is decided on from the radiograph alone the operation must be performed as soon as there is an

the way to the norm

Summary

Hypothesis In the growing child there is a connection between the position of the head of the femur in relation to the acetabulum and the function of the surrounding muscles In particular it is the balance between the adductors and the abductors of the hip that is of significance for the stability of the hip in the frontal plane

Chapter I By an investigation of the hip in myelomeningocele it is shown that acquired dislocation of the hip may develop when a muscular imbalance is present with adductors and flexors functioning better than abductors and extensors

Experiments on hip models provide no demonstration of what happens in growing individuals Experiments on the young of animals have shown that the hamstrings exert a dislocating effect when the hips are flexed and at the same time the knee joints are maintained extended for some length of time However no investigator has demonstrated which muscle imbalance is of more significance under ordinary conditions A valgus hip appears to develop due to impaired osteogenesis in the epiphysis of the trochanter major the result of diminished stimulation by the hip abductors when their function is reduced

A review is presented of the most important literature on the hip joint in cerebral palsy Some studies show that a relation does exist between the stability of the hip and the function of the sorrounding muscles Muscle imbalance with contracture in the adductors flexors m gracilis and hamstrings is cited as dislocating factor Further factors mentioned as causing dislocation of the hip are coxa valga »status hypoplasticus« and retained neonatal reflexes

It should be possible to test the hypothesis presented by examining the results of lengthening and weakening various muscle groups around the hip joints in children with cerebral palsy This could be done by measuring the stability of the hip on a radiograph before and after operation since an examination of the extreme cases will help to elucidate minor deviations from normal

Chapter II Based on the literature a review is provided of the most familiar methods of measuring the stability of the hip in the frontal plane It is concluded that the relation of the head of the femur to Perkins line (Fig 2) is the best way of indicating the stability of the hip among other reasons because the relation is independent of any pelvic tilt around a horizontal axis so that a urograph for example can also be used for the measurement That visible part of the femoral head which has migrated beyond Perkins line is expressed as a percentage of the width of the entire head and is designated the *Migration Percentage (MP)*

It is shown (Table 1) that the measured difference in MP between internal rotation and neutral rotation of the same hip joint is so small that there are no indications for determinations in both rotations when making a radiographic investigation of the MP of the hip

Chapter III The literature does not contain a normal material of hips measured in relation to Perkins line An investigation was therefore made of the correlation between MP and CE angle (Table 2) to determine whether a normal material based on this measurement could

tendo Achilles adds support to the theory of muscle imbalance as a cause of hip migration since a quantitative improvement in gait may accentuate the already existing imbalance when the use of the muscles are not improved qualitatively at the same time

Chapter VI It has now been shown that soft tissue operations may influence the migration of the »cerebral palsy« hip and that the best Results were obtained by lengthening and weakening of the adductors The adductor operations are therefore analyzed in greater detail in the same way as the soft tissue operations were in Chapter V

The first adductor operation gave a median Result of 15 per cent/year (Table 19) while secondary operations gave only 6 5 per cent/year (Table 20)

Unilateral operations among first and secondary operations gave a Result of 11 per cent/year (Table 22) but it seems that the operation exerting a negative influence on the unoperated hip with the non significant Result of 4 per cent/year (Table 23)

The Result of the adductor operations was unaffected by whether the children were para og diplegics or tetraplegics (Table 24) whether they were under the Care of the Danish National Service for the Mentally Retarded or not (Table 25) or whether they were boys or girls (Table 26)

On the other hand the best Results were obtained when the children were under the age of 4 years (Table 27) and when the preoperative MP was more than 40 per cent (Table 28) without it being possible to decide which factors were most significant (Table 29)

The Result of gracilis resections alone is a median value of 2 per cent/year but the fact that in these operations the preoperative MP was only 21 per cent may explain this doubtful Result as in that proportion of the adductor operations where the preoperative MP was likewise less than 40 per cent the Result obtained 5 per cent/year is of the same order of magnitude as in the gracilis resections However the median age at the adductor operations was greater than in the gracilis operations Both statically and dynamically the gracilis operation would not be expected to have any significance as it can only influence the hip when the knee is extended so that it can be the postoperative splintage with abducted legs that has been responsible for the doubtful although positive Result

Chapter VII In order to decide the significance of contracture in the adductors for the MP of the hip the hips were investigated in 95 children prior to the first operation on the adductors and the measurements are correlated with the MP of the *corresponding hips* The measurements were made with 90 per cent flexion in the hip and knee as well as with extended leg to elucidate further whether there is any effect of the gracilis muscle on the hip

Clinical experience shows that muscles and tendons must be subjected to stretch by a certain force in order to grow in length When the agonist is too weak to influence the antagonist the latter must remain »contracted« in relation to *the growth of the child* and as a result the imbalance becomes aggravated A relation would therefore be anticipated between abduction and MP in the hip as brevity of the adductors must signify that the abductors function more weakly

The result of the investigation (Table 30) is that as expected there is a significant correlation but as this is only 0 35 it signifies that the *brevity is not* the primary deforming force The correlation is least when the abduction was measured with legs extended suggesting that the gracilis does not have any great significance for the containment of the hip so that an investigation of the abduction is best *made with flexed* hip and knee joint

A sketch (Fig 13) shows how an adduction contracture in a hip can trigger off such a muscle imbalance It is also shown in a *case history (Fig 14)* how an adductor operation can reduce a dislocated hip in spite of the almost complete absence of brevity in the adductors

indication of commencing subluxation as the hips did not improve spontaneously and as the first adductor operation did not convert subluxated hips into »optimal« hips

An investigation of the hips in all 38 patients before and after all soft tissue operations shows that with a median period of observation of 6½ years 3 hips had become dislocated in spite of the operations and that one hip had been reduced 33 per cent of the hips had improved or maintained their position in relation to the spontaneous migration In relation to the maximum MP experienced 71 per cent improved as a result of operations on muscles and tendons (Table 10 and Figs 10 and 11)

In view of the observation that the stability improved in 20 out of the 25 hips which had migrated more than 50 per cent out of the acetabulum it is concluded that this justifies the effort involved in the treatment without consideration of the level of intelligence and the ambulatory capacity as a dislocation in this group of patients has a considerably incapacitating effect and increases their need for nursing care

Chapter V Since adductor operations are often combined with other soft tissue operations these operations are therefore analyzed as single interventions In order to be able to evaluate changes in MP in relation to time the concept *Migration Index (MI)* is introduced signifying the amount by which the MP of a hip has changed in one year The MI is negative if the femoral head migrates outwards and positive if it migrates inwards The change in preoperative and postoperative MIs thus indicates the *Result of Treatment* expressed as a percentage/year

A total of 1700 children with cerebral palsy have been treated in the Outpatient Department for Handicapped Children at the Rigshospital since 1950 Among those children those 10 are selected who has undergone a total of 19 single gracilis resections a radiographic observation of the hip migration being required both preoperatively and postoperatively The Result found is that the migration of the hips following operation had improved non significantly by 2 per cent/year in relation to the migration prior to operation (Table 12)

A corresponding analysis of 10 resections of the anterior branch of the obturator nerve shows an significant improvement of 4 per cent/year (Table 13) and an examination of the 22 elongations of the hip flexors including the iliopsoas all of which satisfies the above criteria for selection gives a Result of 0 per cent/year (Table 14)

Among those patients at the Orthopaedic Hospital who between 1969 and 1971 underwent a proximal elongation of the hamstrings a total of 43 operations are investigated which satisfies the criteria The significant Result is a median value of 1 per cent/year (Table 15)

Since various soft tissue operations are often performed together with gracilis resection the total of 75 operations are grouped into those with and without simultaneous gracilis resection The Result shows a median effect of 1 per cent/year when the gracilis was involved and 1 per cent/year when the gracilis was not involved at the same time (Table 16)

An operation to improve ambulation such as lengthening of the tendo Achilles is analyzed in a material of 21 operations and gives the unexpected significant Result that the migration was increased by a median value of 4 per cent/year (Table 17)

The positive Result of resection of the anterior branch of the obturator nerve support the finding in Chapter IV that the function of the adductor muscles is of great importance for the migration of the hip joint

The absence of any effect of lengthening the hip flexors agrees with clinical experience that the m iliopsoas in particular does not influence hip migration The poor Result of operations on the hamstrings does not exclude the possibility that these muscles may provoke prenatal dislocation of the hip in frank breech prese
examined were over the age of 4 years The negative Result

prior to operation

The only information that the abduction can provide as to the stability of the hip is that if the passive abduction is reduced to below 30° the femoral head must have migrated outside the acetabular edge A clinical investigation cannot replace a radiographic investigation of the hips as a hip may well be subluxated in a few cases in spite of a range of abduction up to 60°

Chapter VIII In the GENERAL DISCUSSION the most significant results of the investigations are discussed and correlated with the treatment of some of the diseases of the hip in children

In children with cerebral palsy the best Results of adductor operations were obtained at the first operation in children under the age of 4 years and where there was a considerable preoperative MP At the same time however clinical experience shows that this is the group of patients in whom treatment is most difficult in the years of childhood In spite of treatment some of these hips become dislocated after a period of pain and any ambulatory capacity present will be lost

The majority of investigators today consider that laxity of the joint capsule of the hip disposes to congenital subluxation or dislocation When the femoral head is not centered in the acetabulum the effect of the abductors is weakened so that muscle imbalance develops This explains the brevity of the adductors often present later in the course of the disease even after a hip has been reduced following a dislocation Congenital instability of the hip joint might therefore be treated with an elongation and weakening of the adductors in the presence of brevity in these muscles

We know that a relationship exists between osteoarthrosis of the hip and an unstable hip in infancy However so long as we have not examined the relation between MP and osteoarthrosis no basis exists for too rigorous claims as to what is the »normal« hip in children

If we in myelomeningocele aim at containment of the hip joints the primary intervention must be to treat a present muscle imbalance between weak abductors and stronger adductors by for example a tenomyotomy of the adductors

In the GENERAL CONCLUSION the results of the various investigations are set out

In brief it has been shown with the aid of the »cerebral palsy« hip that the head of the femur can be made to migrate inwards in relation to the acetabulum after an adductor operation and it has been shown in addition that the interventions which often accompany the above operation such as lengthening of the m gracilis hip flexors and hamstrings have at most minor effects This must signify that it is either the lengthening or the resulting weakening of the adductors that has the greater significance *for an improvement in hip stability* As it has thus been demonstrated that anterior obturator neurectomy has an effect similar to that obtained by adductor operations and that only a slight relation exists between the magnitude of the brevity of the adductors and the stability of the hip it may be concluded that the hypothesis originally presented is correct

That is that in the growing child there is a connection between the position of the femoral head in the acetabulum and the function of the surrounding muscles In addition the investigation has shown it is in particular the balance between hip adductors and abductors that has significance for the containment of the hip in the frontal plane as weak abductors in contrast to better functioning adductors result in the femoral head migrating outwards in relation to the acetabulum

Resumé

Hypotese Der er sammenhæng mellem caput femoris stilling i forhold til acetabulum og de omgivende musklers funktion i barneårene Specielt er det balancen mellem hoftens adduktorer og abduktorer der har betydning for hoftens stabilitet i frontalplanet

Kapitel I Ved undersøgelsen af hofteleddet ved myelomeningocele er det vist at erhvervede hofteluksationer kan opstå når der er en muskulær imbalance således at adduktorer og fleksorer fungerer bedre end abduktorer og ekstensorer

Eksperimenter på hoftemodeller kan ikke vise hvad der sker hos voksende individer Ved eksperimenter på dyrebørn er det vist at hamstrings (mm ischiocrurales) virker lukserende når hofterne er flekterede og knæene samtidig holdes ekstenderede i længere tid Men ingen eksperimenter har vist hvilken muskelimbalance der har størst betydning under almindelige forhold Valgushoften synes at opstå ved en nedsat osteogenese i trochanter major epifysen på grund af en mindsket stimulation fra hoftens abduktorer når disses funktion er nedsat

Den vigtigste litteratur vedrørende hofteleddet ved cerebral parese gennemgås Enkelte arbejder viser at der er sammenhæng mellem hoftens stabilitet og de omgivende musklers funktion Muskelimbalance med kontraktur i adduktorer fleksorer m gracilis og hamstrings nævnes som dislocerende faktor Desuden nævnes coxa valga »status hypoplasticus« og bevarede neonatale reflekser som årsager til hofteluksation

Det må være muligt at undersøge dette arbejdes hypotese ved at analysere resultaterne af forlængelser og svækkelser af forskellige muskelgrupper omkring hofteleddene hos børn med cerebral parese Dette kan gøres ved at udmåle hofternes stabilitet før og efter operationen idet man ved at undersøge det ekstreme kan erfare om de mindre afvigelser fra det normale

Kapitel II På baggrund af litteraturen gennemgås de mest kendte metoder til udmåling af hoftens stabilitet i frontalplanet Det konkluderes at caput femoris relation til Perkins linie (Fig 2) er den bedste måde at angive hoftens stabilitet bl a fordi relationen er uafhængig af en kipning af bækkenet omkring en vandret akse så f eks urografier også kan anvendes Den del af caputkærnen der er migreret uden for Perkins linie udtrykkes i procent af hele kærnens bredde og benævnes *Migrations Procenten (MP)*

Det vises (Tabel 1) at den målte forskel i MP ved indadrotation og neutralrotation af det samme hofteled er så lille at den ikke kan indicere at man ved en radiologisk undersøgelse af hoftens MP foretager undersøgelsen i begge rotationer

Kapitel III Der findes i litteraturen ikke et normalmateriale af hofter udmålt i forhold til Perkins linie derfor undersøgtes korrelationen mellem MP og CE vinkel (Tabel 2) for om muligt at kunne anvende disse normalmaterialer Da korrelationskoefficienten mellem MP og CE vinkel kun er 0 76 fremstilledes et »normalmateriale« af MPr idet et større antal hofteled blev udmålt på urografier Herfra blev patienter med Wilms tumor neuromusku

prior to operation

The only information that the abduction can provide as to the stability of the hip is that if the passive abduction is reduced to below 30° the femoral head must have migrated outside the acetabular edge A clinical investigation cannot replace a radiographic investigation of the hips as a hip may well be subluxated in a few cases in spite of a range of abduction up to 60°

Chapter VIII In the GENERAL DISCUSSION the most significant results of the investigations are discussed and correlated with the treatment of some of the diseases of the hip in children

In children with cerebral palsy the best Results of adductor operations were obtained in the first operation in children under the age of 4 years and where there was a considerable preoperative MP At the same time however clinical experience shows that this is the group of patients in whom treatment is most difficult in the years of childhood In spite of treatment some of these hips become dislocated after a period of pain and any ambulatory capacity present *will be lost*

The majority of investigators today consider that laxity of the joint capsule of the hip disposes to congenital subluxation or dislocation When the femoral head is not centered in the *acetabulum the effect* of the abductors is weakened so that muscle imbalance *develops* This explains the brevity of the adductors often present later in the course of the disease even after a hip has been reduced following a dislocation Congenital instability of the hip joint might therefore be treated with an elongation and weakening of the adductors in the presence of brevity in these muscles

We know that a relationship exists between osteoarthrosis of the hip and an unstable hip in infancy However so long as we have not examined the relation between MP and osteoarthrosis no basis exists for too rigorous claims as to what is the »normal« hip in children

If we in myelomeningocele aim at containment of the hip joints the primary intervention must be to treat a present muscle imbalance between weak abductors and stronger adductors by for example a tenomyotomy of the adductors

In the GENERAL CONCLUSION the results of the various investigations are set out

In brief it has been shown with the aid of the »cerebral palsy« hip that the head of the femur can be made to migrate inwards in relation to *the acetabulum after an adductor operation* and it has been shown in addition that the interventions which often accompany the above operation such as lengthening of the m gracilis hip flexors and hamstrings have at most minor effects This must signify that it is either the lengthening or the resulting weakening of the adductors that has the greater significance for an improvement in hip stability As it has thus been demonstrated that anterior obturator neurectomy has an effect similar to that obtained by adductor operations and that only a slight relation exists between the magnitude of the brevity of the adductors and the stability of the hip it may be concluded that the hypothesis originally presented is correct

That is that in the growing child there is a connection between the position of the femoral head in the acetabulum and the function of the surrounding muscles In addition the investigation has shown it is in particular the balance between hip adductors and abductors *that has significance for the* containment of the hip in the frontal plane as weak abductors in contrast to better functioning adductors result in the femoral head migrating outwards in relation to the acetabulum

50% uden for acetabulum konkluderes at dette retfærdiggør indsatsen ved behandlingen uafhængigt af intelligens og gangevne idet en luksation forringer denne gruppe af patienter betydeligt og øger plejebehovet

Kapitel V Adduktor operationer er ofte kombinerede med andre bløddelsoperationer der derfor analyseres særskilt For at kunne bedømme ændringen af MP i relation til tiden ind føres et *Migrations Index (MI)* der angiver ændringen af en hoftes MP pr år MI er nega tivt hvis caput vandrer udad og MI er positivt når caput vandrer indad Differencen mel lem det præ og postoperative MI angiver *Resultatet af behandlingen* i procent pr år

Blandt 1700 børn med cerebral parese der fra 1950 er undersøgt i Ambulatoriet for Han dicappede Børn på Rigshospitalet udvælges de 10 børn som ialt har fået udført 19 isolere de gracilis resektioner idet man kræver en radiologisk observation af forløbet af hofternes migration både præ og postoperativt Resultatet bliver at hofternes migration efter opera tionen bedredes 2%/år i forhold til forløbet før operationen (Tabel 12)

Ved en tilsvarende analyse af 10 resektioner af forreste gren af n obturatorius findes et Resultat på 4%/år (Tabel 13) og ved undersøgelse af de 22 forlængelser af hoftefleksorer incl iliopsoas der opfylder udvælgelseskriterierne er Resultatet 0%/år (Tabel 14)

Blandt de patienter der på Ortopædisk Hospital i København fra 1969 til 1971 fik udført en proksimal forlængelse af hamstrings undersøges de 43 operationer der opfylder kriterier ne Resultatet er i middel 1%/år (Tabel 15)

Da de forskellige bløddelsoperationer ofte bliver udført samtidig med en gracilis resek tion opdeles de ialt 75 operationer i dem med og dem uden samtidig gracilis resektion Re sultatet bliver at middel effekten er 1%/år når gracilis var medinddraget og 1%/år, når gracilis ikke samtidig blev reseceret (Tabel 16)

En gangforbedrende operation som en forlængelse af Achillessenen er det analyseres ef ter 21 operationer og giver det uventede signifikante Resultat at migrationen i middel øge des 4% om året (Tabel 17)

Det signifikante positive Resultat af resektion af den forreste gren af n obturatorius sva rer til resultatet af undersøgelserne i Kapitel IV at funktionen af adduktorerne har en stor betydning for hoftens migration

Den manglende effekt af forlængelse af hoftefleksorerne svarer til den kliniske erfaring at specielt iliopsoas ikke påvirker caput femoris relation til acetabulum Det ringe Resultat af operationer på hamstrings udelukker ikke at disse muskler prænatalt ved ren sædestilling kan provokere en hofteluksation idet alle de undersøgte børn var over 4 år Det negative Resultat efter Achillesseneforlængelserne underbygger teorien om en muskelimbalance som årsag til hofternes vandring idet en kvantitativt øget gang kan accentuere den i forvejen be stående muskelimbalance omkring hofterne når brugen af musklerne ikke samtidig bedres kvalitativt

Kapitel VI Det er nu vist at bløddelsoperationer kan påvirke den »cerebral paretiske« hof tes migration og at det var en forlængelse og svækkelse af adduktorerne der gav de største Resultater Adduktor operationerne analyseres derfor nærmere på samme måde som blød delsoperationerne i Kapitel V blev det

Den første adduktor operation gav et Resultat på i middelværdi 15%/år (Tabel 19) hvorimod reoperationer kun gav 6 5%/år (Tabel 20)

De ens dige operationer blandt alle adduktor operationerne gav et middel Resultat på 11% år (Tabel 22) men samtidig påvirkedes den modsatte ikke opererede hofte i negativ retning med et Resultat på 4%/år (Tabel 23)

Det havde ingen betydning for Resultatet af adduktor operationerne om børnene var para eller diplegikere eller tetraplegikere (Tabel 21) om de var under Åndssvageforsorgen

lære lidelser og børn med urinvejsinfektioner fra det første leveår ekskluderet og kun hofte billeder i neutral abduktion adduktion blev anvendt Da udgangsmaterialet er børn med suspekt eller manifest urologisk lidelse må materialet trods selektion være belastet af hof ter der ikke er »optimale« (Tabel 3)

Hos børn under 4 år findes at caputkærnen er helt dækket af acetabulum i 102 af 108 hofteled hvilket må betyde at Perkins linie repræsenterer den maksimale laterale be grænsning for caputkærnen ved den »optimale« hofte i denne aldersgruppe Fra 4 til 16 års alderen må højst 5% af kærnen nå uden for linien hvis hoften skal anses for at være »opti mal« idet dette er tilfældet i 159 af 247 hofter svarende til næsten ⅔ af hofterne Denne be grænsning er kun foreløbig til vi ved mere om relationen mellem MP og coxarthrose

Ved en sammenligning mellem de samme hofters CE vinkler og MPr findes at en CE vin kel < 20° angiver at hoften hos et barn over 4 år ikke er »optimal« (Tabel 4) Derimod ud trykker en CE vinkel ≥ 20° intet sikkert om hoftens stabilitet Tilsvarende findes en korrela tionskoefficient på kun -0 282 mellem CE vinkler ≥ 20° og de tilsvarende MPr

Derefter defineres terminologien *Migrations Procenten (MP)* angiver hvor stor en del af caputkærnen (udtrykt i procent) der på et frontalt røntgenbillede af hofterne er vandret uden for Perkins linie (= acetabularranden) Udmålingen foretages horisontelt i forhold til bækkenet *Migrationen* defineres som forskellen mellem to MPr udmålt på to forskellige tidspunkter *Subluksation* betyder at MP er mindst 33% *Luksation* og *dislocation* betyder at MP er 100% *Dysplasi* anvendes i perioden for caputkærnen endnu er synlig og betyder at acetabulum er stejl med en vigende rand som var den blevet presset under væksten

Det vises herefter hvordan forløbet af hofternes vandring kan registreres i et koordinatsy stem med MPr i relation til tiden (Fig 5) Resultatet af operationerne angivet ved en æn dring af hofternes migration kan visualiseres i et diagram hvor begge akser har samme en hed (Fig 6)

Kapitel IV Den »normale« hoftes spontane migration der er under 1% om året fremgår direkte af Tabel 3 Heraf ses også at den »normale« hofte ikke subluksérer

Blandt 441 patienter med cerebral parese indlagt på Ortopædisk Hospital i København i perioden 1 januar 1969 til 1 juli 1971 blev de 38 børn under 19 år udvalgt der i perioden havde en subluksèret hofte og af den grund fik udført adduktor operation eventuelt i for bindelse med andre bløddelsoperationer men ikke samtidig med forlængelse af hamstrings eller femurosteotomier

I 39 tilfælde findes så mange røntgenbilleder at hofternes vandring kan bestemmes før og efter den første adduktor operation En undersøgelse af disse hofter viser at subluksationen oftest var erhvervet (Fig 7 og Tabel 5) og at de fleste af hofterne vandrede indad igen efter den første adduktor operation (Fig 8 og Tabel 6)

Sharrard et al fandt i 1975 at den første adduktor operation resulterede i at 75% af hofterne fik stabiliteten bedret eller vedligeholdt Deres undersøgelse bekræftes ved en ana lyse af de foregående 39 hofter samt 18 hofter uden præoperativ observation (Fig 9 og Ta bel 8) med et resultat af operationen på 57% Desuden viser undersøgelsen at hvis man vil le behandle alene på et røntgenbillede bør man operere så snart man konstaterer en truen de subluksation idet hofterne ikke bedredes spontant og idet den første adduktor opera tion ikke ændrede subluksérede hofter til »optimale« hofter

En undersøgelse med i middel 6½ års observationstid af alle 38 patienters hofter før og

gration I forhold til den maksimale MP hofterne var [illegible]
muskel og seneoperationer (Tabel 10 og Fig 10 og 11)

På baggrund af at stabiliteten bedredes hos 20 af de 25 hofter der var vandret mindst

50% uden for acetabulum konkluderes at dette retfærdiggor indsatsen ved behandlingen uafhængigt af intelligens og gangevne idet en luksation forringer denne gruppe af patienter betydeligt og oger plejebehovet

Kapitel V Adduktor operationer er ofte kombinerede med andre bloddelsoperationer der derfor analyseres særskilt For at kunne bedømme ændringen af MP i relation til tiden indfores et *Migrations Index (MI)* der angiver ændringen af en hoftes MP pr år MI er negativt hvis caput vandrer udad og MI er positivt når caput vandrer indad Differencen mellem det præ og postoperative MI angiver *Resultatet af behandlingen* i procent pr år

Blandt 1700 born med cerebral parese der fra 1950 er undersogt i Ambulatoriet for Han

Ved en tilsvarende analyse af 10 resektioner af forreste gren af n obturatorius findes et Resultat på 4%/år (Tabel 13) og ved undersogelse af de 22 forlængelser af hoftefleksorer incl iliopsoas der opfylder udvælgelseskriterierne er Resultatet 0%/år (Tabel 14)

Blandt de patienter der på Ortopædisk Hospital i Kobenhavn fra 1969 til 1971 fik udfort en proksimal forlængelse af hamstrings undersoges de 43 operationer der opfylder kriterierne Resultatet er i middel 1%/år (Tabel 15)

Da de forskellige bloddelsoperationer ofte bliver udfort samtidig med en gracilis resektion opdeles de ialt 75 operationer i dem med og dem uden samtidig gracilis resektion Resultatet bliver at middel effekten er 1%/år når gracilis var medinddraget og 1%/år når gracilis ikke samtidig blev reseceret (Tabel 16)

En gangforbedrende operation som en forlængelse af Achillessenen er det analyseres efter 21 operationer og giver det uventede signifikante Resultat at migrationen i middel oges 4% om året (Tabel 17)

Det signifikante positive Resultat af resektion af den forreste gren af n obturatorius svarer til resultatet af undersogelserne i Kapitel IV at funktionen af adduktorerne har en stor betydning for hoftens migration

Den manglende effekt af forlængelse af hoftefleksorerne svarer til den kliniske erfaring at specielt il opsoas ikke påvirker caput femoris relation til acetabulum Det ringe Resultat af operationer på hamstrings udelukker ikke at disse muskler prænatalt ved ren sædestilling kan provokere en hofteluksation idet alle de undersogte born var over 4 år Det negative Resultat efter Achillessenefforlængelserne underbygger teorien om en muskel imbalance om årsag

Den første adduktor operation gav et Resultat på i middelværdi 15%/år (Tabel 19) hvorimod reoperationer kun gav 6 5%/år (Tabel 20)

De ensidige operationer blandt alle adduktor operationerne gav et middel Resultat på 11%/år (Tabel 22) men samtidig påvirkedes den modsatte ikke opererede hofte i negativ retning med et Resultat på 4%/år (Tabel 23)

Det havde ingen betydning for Resultatet af adduktor operationerne om børnene var para eller diplegikere eller tetraplegikere (Tabel 24) om de var under Åndssvageforsorgen

lære lidelser og børn med urinvejsinfektioner fra det første leveår ekskluderet og kun hofte billeder i neutral abduktion adduktion blev anvendt Da udgangsmaterialet er børn med suspekt eller manifest urologisk lidelse må materialet trods selektion være belastet af hofter der ikke er »optimale« (Tabel 3)

Hos børn under 4 år findes at caputkærnen er helt dækket af acetabulum i 102 af 108 hofteled hvilket må betyde at Perkins linie repræsenterer den maksimale laterale begrænsning for caputkærnen ved den »optimale« hofte i denne aldersgruppe Fra 4 til 16 års alderen må højst 5% af kærnen nå uden for linien hvis hoften skal anses for at være »optimal« idet dette er tilfældet i 159 af 247 hofter svarende til næsten ⅔ af hofterne Denne begrænsning er kun foreløbig til vi ved mere om relationen mellem MP og coxarthrose

Ved en sammenligning mellem de samme hofters CE vinkler og MPr findes at en CE vinkel < 20° angiver at hoften hos et barn over 4 år ikke er »optimal« (Tabel 4) Derimod udtrykker en CE vinkel ≥ 20° intet sikkert om hoftens stabilitet Tilsvarende findes en korrelationskoefficient på kun 0 282 mellem CE vinkler ≥ 20° og de tilsvarende MPr

Derefter defineres terminologien *Migrations Procenten (MP)* angiver hvor stor en del af caputkærnen (udtrykt i procent) der på et frontalt røntgenbillede af hofterne er vandret uden for Perkins linie (= acetabularranden) Udmålingen foretages horisontelt i forhold til bækkenet *Migrationen* defineres som forskellen mellem to MPr udmålt på to forskellige tidspunkter *Subluksation* betyder at MP er mindst 33% *Luksation og dislocation* betyder at MP er 100% *Dysplasi* anvendes i perioden før caputkærnen endnu er synlig og betyder at acetabulum er stejl med en vigende rand som var den blevet presset under væksten

Det vises herefter *hvordan forløbet af hofternes vandring kan registreres i et koordinatsystem* med MPr i relation til tiden (Fig 5) Resultatet af operationerne angivet ved en ændring af hofternes migration kan visualiseres i et diagram hvor begge akser har samme enhed (Fig 6)

Kapitel IV Den »normale« hoftes spontane migration der er under 1% om året fremgår direkte af Tabel 3 Heraf ses også at den »normale« hofte ikke sublukserer

Blandt 441 patienter med cerebral parese indlagt på Ortopædisk Hospital i København i perioden 1 januar 1969 til 1 juli 1971 blev de 38 børn under 19 år udvalgt der i perioden havde en sublukseret hofte og af den grund fik udført adduktor operation eventuelt i forbindelse med andre bløddelsoperationer men ikke samtidig med forlængelse af hamstrings eller femurosteotomier

I 39 tilfælde findes så mange røntgenbilleder at hofternes vandring kan bestemmes før og efter den første adduktor operation En undersøgelse af disse hofter viser at subluksationen oftest var erhvervet (Fig 7 og Tabel 5) og at de fleste af hofterne vandrede indad igen efter den første adduktor operation (Fig 8 og Tabel 6)

Sharrard et al fandt i *1975* at den første *adduktor operation resulterede i* at 75% af hofterne fik stabiliteten bedret eller vedligeholdt Deres undersøgelse bekræftes ved en analyse af de foregående 39 hofter samt 18 hofter uden præoperativ observation (Fig 9 og Tabel 8) *med et resultat af operationen på 57%* Desuden viser undersøgelsen at hvis man ville behandle alene på et røntgenbillede bør man operere så snart man konstaterer en truende subluksation idet hofterne ikke bedredes spontant og idet den første adduktor operation ikke ændrede sublukserede hofter til »optimale« hofter

En undersøgelse med i middel 6½ års observationstid af alle 38 patienters hofter før og efter alle bløddelsoperationer viser at 3 hofter lukserede trods operationer og én hofte blev reponeret 33% af hofterne var bedret eller bevaret på plads i forhold til den spontane migration I forhold til den maksimale MP hofterne var sæde for *var 71% bedrede alene ved* muskel og seneoperationer (Tabel 10 og Fig 10 og 11)

På baggrund af at stabiliteten bedredes hos 20 af de 25 hofter der var vandret mindst

tomi på adduktorerne ved tilstedeværende brevitet af disse

Vi ved at der er en relation mellem hoftearthrose og en instabil hofte i barndommen Men [illegible] længe vi ikke har undersøgt sammenhængen mellem MP og arthrose, er der ikke baggrund for at være for rigoristiske i vores krav til den »normale« barnehofte

Hvis vi ved myelomeningocele ønsker at bevare hofterne stabile, må den primære behandling være at behandle en tilstedeværende imbalance mellem svage abduktorer og stærkere adduktorer med for eksempel en tenomyotomi på adduktorerne

GENEREL KONKLUSION hvor resultaterne af de forskellige undersøgelser refereres

Til slut sammenfattes at det ved hjælp af den »cerebral paretiske« hofte er vist, at caput femoris kan bringes til at vandre indad i forhold til acetabulum efter en adduktor operation og at det desuden er vist at de ofte ledsagende indgreb som en forlængelse af m gracilis hoftefleksorer og hamstrings højst har en mindre effekt Dette må betyde, at det enten er forlængelsen eller den samtidige svækkelse af adduktorerne der har den største betydning for bedringen af hofternes stabilitet Da det desuden er vist, at en neurectomi af n obturatorius forreste gren har en effekt af samme størrelse som en adduktor operation og da det er vist at der kun er en ringe sammenhæng mellem graden af brevitet af adduktorerne og hoftens stab [illegible]

[illegible] at det specielt er balancen mellem hoftens adduktorer og abduktorer, der har betydning for hoftens stabilitet i frontalplanet idet svage abduktorer i forhold til bedre fungerende adduktorer bevirker at caput femoris vandrer udad i forhold til acetabulum

eller ej (Tabel 25) og om de var piger eller drenge (Tabel 26)

Derimod findes at de bedste Resultater opnåedes når børnene var under 4 år (Tabel 27) og den præoperative MP var over 40% (Tabel 28) uden at det kan afgøres hvilken faktor der havde den største betydning for Resultatet (Tabel 29)

Resultatet af gracilis resektionerne er i middel 2%/år men det at den præoperative MP ved disse operationer kun var 21% kan forklare det tvivlsomme Resultat Idet Resultatet af den del af adduktor operationerne hvor den præoperative MP ligeledes var under 40% er i samme størrelsesorden på 5%/år Dog var middel alderen større ved adduktor operationerne end ved gracilis resektionerne Statisk og dynamisk ville man ikke vente nogen betydning af m gracilis på hofteleddet da musklen kun er udspændt når knæet ekstenderes og det kan derfor være den postoperative bandagering med abducerede ben der har bevirket det tvivlsomme men dog positive Resultat

Kapitel VII For at afgøre betydningen af en tilstedeværende forkortning af adduktorerne for hoftens MP blev 95 børns hofteled undersøgt før den første adduktor operation og målingen sættes i relation til den tilsvarende hoftes MP Målingerne blev udført med 90° fleksion i hofte og knæ samt med ekstenderede ben for eventuelt yderligere at kunne belyse m gracilis indflydelse på hoften

Ud fra kliniske erfaringer skal muskler og sener udspændes med en vis kraft for at kunne vokse i længden Når agonisten er for svag til at påvirke antagonisten må denne i forhold til barnets vækst blive for kort og dette forværrer imbalancen Man vil derfor vente at der er en sammenhæng mellem hoftens abduktion og MP idet en brevitet i adduktorerne må betyde at abduktorerne er svagere fungerende

Undersøgelsen gav som resultat (Tabel 30) at der som ventet findes en signifikant korrelation men da den kun er 0 35 betyder det at det ikke er breviteten der primært er den deformerende kraft Korrelationen er mindst når abduktionen blev målt med strakte ben dette tyder mod at gracilis har en større betydning for hoftens kvalitet og derfor foretages en undersøgelse af abduktionen bedst med flekterede hofte og knæled

Med en tegning (Fig 13) vises hvordan en adduktionskontraktur i en hofte kan udløse en sådan muskelimbalance Og det vises ved en sygehistorie (Fig 14) hvordan en adduktor operation kan reponere en sublukseret hofte til trods for at der før operationen næsten ikke fandtes brevitet i adduktorerne

Det eneste abduktionen kan fortælle om hoftens stabilitet er at hvis den passive abduktion er nedsat til under 30° må caput femoris være vandret uden for acetabularhjørnet Undersøgelsen kan ikke erstatte en røntgenundersøgelse af hofterne idet en hofte godt kan være sublukseret i enkelte tilfælde til trods for at hoften kan abduceres 60°

Kapitel VIII GENEREL DISKUSSION hvor de væsentligste resultater af undersøgelserne diskuteres og sættes i relation til behandlingen af nogle hoftelidelser i barneårene

Ved cerebral parese opnåedes de bedste radiologiske Resultater af adduktor operationer ved den første operation hos børn under 4 år og ved en stor præoperativ MP Men samtidig er det en klinisk erfaring at det er denne patientgruppe der op gennem årene er vanskeligst at behandle Eventuelt trods behandling lukserer nogle af disse børns hofter efter en periode med smerter og en mulig gangfunktion ophører

Løshed af hofteleddet anses i dag af de fleste for at disponere til den medfødte subluksation og luksation Når caput femoris ikke er centreret i acetabulum svækkes effekten af abduktorerne hvorved der opstår en muskelimbalance Dette forklarer den brevitet af adduktorerne der ofte er til stede senere i forløbet selv efter hoften er reponeret efter en luksation

En konsekvens af vores nuværende viden må være at der gøres en tilstrækkelig tenomyo

CONTENTS

CHAPTER I — INTRODUCTION

History

Primary malignant bone tumours account for less than 1 % of all malignant tumours in man in all ages[26,131] Osteosarcoma occurs predominantly during the first three decades of life and is the most common primary malignant bone tumour in this age group[14,26,61,67,77,79,86,104,116,118,131,147]

Smith and Dawson[123] reported in 1924 that evidence has been found dating the occurrence of primary bone tumours as far back as the fifth Egyptian dynasty The term osteosarcoma was used by Boyer[6] [redacted] early as 1807 and a first attempt at classifying bone tumours into malignant and benign forms was presented by Nelaton[92] in 1860 More systematic classifications have later been published by Codman[20] [redacted] 1925, Scarff[117] in 1937, Ewing[39] in 1939, and Cade[13] in 1947, and more recently by Lichtenstein[79] in 1952, Dahlin[26] in 1957, and Jaffe[65] in 1958

The term osteogenic sarcoma [redacted] encountered early in the literature without any clear distinction from chondrosarcoma and fibrosarcoma, which were often included in this concept Some authors have used the term osteogenic sarcoma as a collective designation for different malignant primary tumours of bone,[81,82,83] whereras others use the term as synonymous to osteosarcoma[28,61,79,86,94,97,136] In recent years the term osteogenic sarcoma has been virtually ousted by osteosarcoma to designate the specific primary malignant bone tumour which histopathologically is characterized by osteoid-producing malignant bone cells[26,78,116,136] An annual incidence of 2 cases per million inhabitants has been reported[74,103]

Pathology

It [redacted] often difficult to make a diagnosis of osteosarcoma on the basis of the histopathological findings, especially as the bone tissue contains cells of many different types and varying stages of maturity It has been suggested that the tumour cells originate from immature osteogenic mesenchymal cells, in combination with often completely anaplastic connective tissue cells of spindle shaped type[14,28,29,36,80,82] Giant cells of both malignant and benign type are frequently seen, but an absolute condition for a diagnosis of osteosarcoma is the presence of osteoid[26,28,61,79,81,83,136]

Tumours designated as osteosarcoma may be further distinguished according to the predominant cell type into an osteoblastic, chondroblastic or fibroblastic variety In large series such as those presented by Dahlin,[26–29] about 50 % of the tumours are of the osteoblastic type while the chondroblastic and fibroblastic types account for about 25 % each Different portions of the solid tumour may present an entirely different histological picture, which makes it difficult to differentiate osteosarcoma from chondrosarcoma or fibrosarcoma, and sometimes also from wholly benign conditions like aneurysmal bone cyst, fibrous dysplasia or chronic osteomyelitis[26,61,79]

The degree of malignancy can be assessed by examining the degree of differentiation of the tumour cells as reflected by nuclear appearance and mitotic frequency Broders [redacted] al.[9] have described such a grading system based on a four-grade scale in which grade IV represents the least differentiated tumour type Another malignancy grading system based on mitotic frequency has been presented by Price[101]

CHAPTER 1 – INTRODUCTION

History

Primary malignant bone tumours account for less than 1 % of all malignant tumours in man in all ages [26,131] Osteosarcoma occurs predominantly during the first three decades of life and is the most common primary malignant bone tumour in this age group [14,26,61,67,77,79,86,104,116,118,131,147]

Smith and Dawson[123] reported in 1924 that evidence has been found dating the occurrence of primary bone tumours as far back as the fifth Egyptian dynasty The term osteosarcoma was used by Boyer[6] as early as 1807 and a first attempt at classifying bone tumours into malignant and benign forms was presented by Nelaton[92] in 1860 More systematic classifications have later been published by Codman[20] in 1925, Scarff[117] in 1937, Ewing[39] in 1939, and Cade[13] in 1947, and more recently by Lichtenstein[79] in 1952, Dahlin[26] in 1957, and Jaffe[61] in 1958

The term osteogenic sarcoma is encountered early in the literature without any clear distinction from chondrosarcoma and fibrosarcoma, which were often included in this concept Some authors have used the term osteogenic sarcoma as a collective designation for different malignant primary tumours of bone,[81,82,83] whereras others use the term as synonymous to osteosarcoma [28,61,79,86,94,97,136] In recent years the term osteogenic sarcoma has been virtually ousted by osteosarcoma to designate the specific primary malignant bone tumour which histopathologically is characterized by osteoid-producing malignant bone cells [28,78,118,136] An annual incidence of 2 cases per million inhabitants has been reported [74,103]

Pathology

It is often difficult to make a diagnosis of osteosarcoma on the basis of the histopathological findings especially as the bone tissue contains cells of many different types and varying stages of maturity It has been suggested that the tumour cells originate from immature osteogenic mesenchymal cells, in combination with often completely anaplastic connective tissue cells of spindle-shaped type [14, 28, 29, 36, 80, 82] Giant cells of both malignant and benign type are frequently seen, but an absolute condition for a diagnosis of osteosarcoma is the presence of osteoid [26,28,61,79,81,83,136]

Tumours designated as osteosarcoma may be further distinguished according to the predominant cell type into an osteoblastic, chondroblastic or fibroblastic variety In large series, such as those presented by Dahlin,[26-29] about 50 % of the tumours are of the osteoblastic type while the chondroblastic and fibroblastic types account for about 25 % each Different portions of the solid tumour may present an entirely different histological picture, which makes it difficult to differentiate osteosarcoma from chondrosarcoma or fibrosarcoma, and sometimes also from wholly benign conditions like aneurysmal bone cyst, fibrous dysplasia or chronic osteomyelitis [26,61,79]

The degree of malignancy can be assessed by examining the degree of differentiation of the tumour cells as reflected by nuclear appearance and mitotic frequency *Broders et al*[9] have described such a grading system based on a four-grade scale in which grade IV represents the least differentiated tumour type Another malignancy grading system based on mitotic frequency has been presented by Price [101]

Diagnosis

The diagnosis of osteosarcoma is based on both clinical, radiological and histopathological findings Somewhat varying meanings have been attached to the term classical osteosarcoma in the literature, but in the present work it is used to define intraosseous osteosarcoma in young individuals, usually under 30 years of age, with a peak incidence during the second decade of life often coinciding with the pubertal growth spurt The most common site of the tumour is the metaphyseal region of the long bones and a predominance has been noted among males The radiological findings often present a typical pattern with destructive tumour growth through the cortex Frequent findings are osteolysis and osteosclerosis, as well as the formation of bony spicula and the separation of the periosteum producing what is known as Codman's triangle [26,61,79]

Parosteal and periosteal variants of osteosarcoma have an entirely different clinical course with a higher survival rate [30,36,81,144,145] The histopathological picture in these tumour forms is marked by considerably higher differentiation [144,145] Such tumours, as well as extraosseous,[107] multiple,[2,43] and secondary forms of osteosarcoma such as those resulting from irradiation or Paget's disease are usually excluded from the concept of classical osteosarcoma in the literature [81]

Material

The various investigations comprising the present study were partly based on different clinical series, which are presented in Table I The term Contemporary Group indicates that this group of patients is contemporary to the adjuvant therapy initiated in the 1970's, whereas the term Historical Group refers to the group of patients predating the introduction of such treatment

Table I Clinical series reported in Papers I–VI

Paper no	Time period	Geographical area	No of patients	Group	Adjuvant therapy	
I	1938–1959	Karolinska Hospital	105	–	–	
II	1952–1972	"	35	Historical	–

V	1972–1974	Sweden	44	Contemporary	interferon	(21)
VI	1976–1979	Karolinska Hospital	15	–	interferon	(15)

Patients with classical primary osteosarcoma were included in all series Diagnosis was consistently based on both clinical and radiological findings and on light microscopic examination of tumour specimens In every case included in the series histological examination was carried out by two independent pathologists both thoroughly familiar with tumour diagnostics

No patient included in the series had any signs of metastases at the time of diagnosis The X-ray films of the initial lung examination were re-examined in every single case. Lung tomography or scanning was not performed in any series to exclude patients who could be expected to have a poorer prognosis

The size of the primary tumour was evaluated in collaboration with a radiologist by measuring the greatest diameter visualized by X-ray films in different views Type and duration of symptoms were elicited from the clinical records Blood tests were performed on admission to hospital, before treatment was initiated

Background and aims of the study

For the past several decades the 5-year survival rates for patients with primary osteosarcoma have ranged between 10 % and 20 %[15,49,81,115] Treatment has for decades consisted in surgery or radiation, [illegible]r a combination of both[49] In the early 1970's various kinds of adjuvant therapy were introduced in an attempt to improve survival[24,64,128] Initially excellent results were reported for chemotherapy, but these were based on very small and often selected series with a short period of observation[42] With increased observation periods different centres have reported highly varying effects of this treatment[13]

Starting in 1972, patients admitted [illegible] the Karolinska Hospital without signs of metastatic spread at the time of diagnosis have been given human leukocyte interferon as adjuvant therapy for a period of 18 months[129] The project was started [illegible] a pilot study and the initial results showed a considerably higher survival rate in comparison with a historical control group[128] The study has since been extended and at present comprises 42 patients

No studies have been published using randomized treatment protocols to compare adjuvant treatment of osteosarcoma (high-dose cytostatics or interferon) with non adjuvant treatment Evaluation of the metastasis-free rate and survival has consequently been based on historical control series[15,24,49,56,64,115]

During recent years the validity of such historical control series has been called in question[50,81,113,122,139] One reason is that diagnosis in recent years presumably is made at an earlier stage and that more active treatment has been adopted especially in cases with metastat...

... therapy in osteosarcoma[50,81,113] The present work was initiated in an attempt to test the reliability of historical controls in clinical trials in osteosarcoma and [illegible] elucidate the possible influence of a number of different factors on its course

The following factors were studied Biopsy, certain prognostic factors (age, sex, type and duration of symptoms, tumour size and site, tumour pathology, primary tumour treatment, treatment delay, treatment of metastases), hormonal and metabolic factors (longitudinal growth, dental development, growth hormone and ... glucose tole... cyte and [illegible] ... transferase, ... phosphatase)

The primary aims of the present study were

1 To investigate the risks of open biopsy in the diagnosis of osteosarcoma
2 To study the value and reliability of historical control series by an analysis of factors assumed to affect prognosis
3 To compare a historical and a contemporary group with respect to metastasis free rate and survival in relation to prognostic factors
4 To study the internal and mutual relationship between certain prognostic factors and blood variables
5 To study longitudinal growth and dental development in osteosarcoma patients
6 To study glucose metabolism in osteosarcoma patients by the glucose infusion test and to determine growth hormone and somatomedin levels

The effect of biopsy on survival of patients with osteosarcoma (I)

Between 1938 and 1959 a consecutive series of 105 patients with primary osteosarcoma without evidence of metastatic spread at the time of diagnosis was treated in the Karolinska Hospital The histopathological and radiological findings in this series have been reported in an earlier study.[40] The patients selected from this series for the present study were all under 30 years of age, and had a tumour located in the metaphyseal region of a long bone which had been removed by radical surgery, i e amputation of the limb or disarticulation No patient had received any kind of adjuvant chemotherapy

Fifty-seven patients selected by these criteria could be classified as having classical primary osteosarcoma These patients were divided into two groups Group I includes 24 patients who had an amputation without previous biopsy In these cases diagnosis was based only on clinical and radiological findings and subsequently verified by analysis of operation specimens In Group II, comprising 33 patients, diagnosis was based on analysis of biopsy material In 8 of these cases frozen sections were obtained with or without vascular occlusion by a proximally placed tourniquet immediately prior to amputation In the remaining 25 cases a two-stage procedure was adopted with a mode of 4 days between open biopsy and radical surgery

The two main groups were wholly comparable with respect to such factors as age (mean age 16 3 and 15 7 years, respectively) and sex (42 % females in both groups), and similar with regard to tumour site and treatment Seven patients in Group I and as many in Group II had received preoperative radiation therapy. The radiation dose varied individually and no standard regimen had been followed

All of the patients had been followed up for more than 5 years and there was no difference in the survival rate for the two groups at this time The 5-year survival rate was 21 % in both groups regardless of whether or not biopsy had been done Analysis of the patients who survived for 5 years would seem to indicate radical surgery as a common denominator

Can historical controls be used in current clinical trials in osteosarcoma?

Analysis of prognostic factors (II)

Two groups of patients with osteosarcoma of the long bones without evidence of metastases at the time of diagnosis were analyzed with respect to factors assumed to influence prognosis One was a historical group comprising 35 patients treated at the Karolinska Hospital during the years 1952–1972, the other a contemporary group including all of the 44 patients treated for osteosarcoma in Sweden during the period 1972–1974 This latter group includes 21 patients admitted to the Karolinska Hospital who received adjuvant therapy with human leukocyte interferon

The clinical records tumour slides and X-ray films of both primary tumour and lungs were reviewed independently by the pathologists and clinicians included in a National Cancer Institute (NCI) team visiting Sweden in May, 1976 A unanimous diagnosis of primary osteosarcoma was reached for the 35 patients subsequently included in the historical group and the 44 patients comprising the contemporary group

An analysis of prognostic factors showed the two series to be comparable in age, with

The primary aims of the present study were

1 To investigate the risks of open biopsy in the diagnosis of osteosarcoma

2 To study the value and reliability of historical control series by an analysis of factors assumed to affect prognosis

3 To compare a historical and a contemporary group with respect to metastasis-free rate and survival in relation to prognostic factors

4 *To study the internal and mutual relationship between certain prognostic factors* and blood variables

5 To study longitudinal growth and dental development in osteosarcoma patients

6 To study glucose metabolism in osteosarcoma patients by the glucose infusion test, and to determine growth hormone and somatomedin levels

group when the tumour dose exceeded 45 Gy The percentage of patients treated with this dose was twice as high in this group Disarticulation was more often performed in the historical group, whereas amputation was more common in the contemporary group

The differences that could be noted between the two groups with respect to prognostic factors corresponded with the observed differences in metastasis-free rate and survival

The results of this study indicate that there may be a risk involved in using historical controls when evaluating the effect of adjuvant therapy in osteosarcoma, especially when the series are small and the observation period is short

Correlation between prognostic factors and blood variables (IV)

Prognostic factors and blood chemistry were recorded at the time of diagnosis, prior to any treatment, in a consecutive series of 33 patients with primary classical osteosarcoma and scheduled for an 18 month course of adjuvant interferon therapy at the Karolinska Hospital All patients with clinical evidence of metastases on admission were excluded from the series

Analysis of certain blood variables such as haemoglobin, leukocyte and thrombocyte counts, albumin, haptoglobin, aspartate aminotransferase (Asat), alanine aminotransferase (Alat) and immunoglobulins produced values within the normal range Both the erythrocyte sedimentation rate and the alkaline phosphatase activity were slightly increased, but for this latter blood variable it is very difficult to define reliable normal values for growing individuals

Analysis of prognostic factors showed that one-third of the patients were female, while the average age for the total series was 20 years and the average duration of symptoms 4 months The tumours averaged 10 cm in diameter and in 13 patients were located distally to the knee or elbow The analysis moreover showed a prevalence of osteoblastic high-grade tumours

The recorded prognostic factors were subsequently related to each other and to the analyzed blood variables The results of this study show that female patients had a higher incidence of less malignant more differentiated, fibroblastic tumour types ($p < 0.05$), which are assumed to have a better prognosis A distal tumour site was more common for smaller tumours and was found to have less influence on the recorded blood variables ($p < 0.001$)

Endocrinology

Longitudinal growth and dental development (V)

Between the years 1972–1974 a total of 44 patients (31 males and 13 females) were registered in Sweden under the diagnosis of osteosarcoma without signs of metastatic spread at that time Information on longitudinal growth from birth until the age of diagnosis was obtained from the records of child health centres and school health services where body height was registered at regular intervals These data provided complete growth curves for 19 patients (9 boys and 10 girls)

Analysis of height measurements at 8.0 years when growth is expected to be linear, and at the time of diagnosis – which occurred at a mean age of 13 years for both boys and girls in the series – showed entirely normal growth on comparison with growth curves for other Swedish children at those ages[137] At age 8 a mean height of 128.4 cm was noted for male patients as compared to 128.6 cm for their controls The corre

a mean age of 17 years for the historical and 18 years for the contemporary group Female patients were proportionally fewer in the contemporary group (1 2 4 as compared to 1 1 7), but the difference was statistically not significant Pain was the most frequent presenting symptom in both groups, noted for all patients in the historical and 86 % of the contemporary group The average duration of symptoms was 3 months in both groups, but the incidence of symptoms was significantly higher in the historical group Similarly, ▪ significantly larger tumour size (13 cm as compared to 9 cm) was found in the historical group A tumour size of more than 10 cm was found in no less than 64 % of the patients in this group A significantly higher incidence of poorly differentiated tumours was also noted in the historical group, which moreover showed a tendency toward a more proximal location of the tumour

The study consequently disclosed differences between the two groups with respect to factors which might influence the prognosis The incidence of unfavourable prognostic factors was higher in the historical than in the contemporary group

Metastases and survival (III)

The historical and contemporary groups described in the preceding study (II) did not permit a valid comparison of the metastasis-free and survival rates since the contemporary group included 21 patients who had received adjuvant interferon therapy Their exclusion left a contemporary group of 23 patients who did not receive any adjuvant therapy for comparison with the 35 patients in the historical group

All patients were followed up for at least 2 5 years at which time the metastasis free rate was assumed to have attained steady state The incidence of patients without metastases in the contemporary group was 31 % at this time, as against 14 % in the historical group A similar relationship could be noted with regard to the survival rate which was twice as high for the contemporary group after 2 5 years follow up In addition a delayed plateau phase was noted for the contemporary group producing a displacement of the survival curve as compared to the historical group This can be ascribed to the considerably more active approach adopted in the contemporary group in the treatment of lung metastases with both pulmonary surgery and high dose chemotherapy Half of the patients in this group but none in the historical group had received surgical treatment for such metastases Furthermore 4 patients in the contemporary group had received high-dose chemotherapy as compared to none in the historical group Radiation therapy was given to some patients in either group and in this respect the two groups were comparable

Mean survival time from biopsy to death from the tumour was 19 months for the contemporary group and 13 months for the historical group corresponding to the difference observed between the two groups with respect to the metastasis free rate

Analysis of prognostic factors disclosed that the historical group contained larger (13 cm as compared to 6 cm) and more malignant tumours (71 % osteoblastic Grade IV tumours as compared to 48 %) Similarly a proximal tumour site was more common in the historical group, even though about 75 % of all tumours in both groups were located in the knee region Both the sex ratio showing about one-third of the patients to be female, and the age distribution were comparable in the two groups A higher incidence of symptoms was noted for patients in the historical group who also had shorter intervals between lung X-ray check ups

Primary treatment of the tumour was largely the same in the two groups with the exception of a higher incidence of pre-operative radiation therapy in the contemporary

group when the tumour dose exceeded 45 Gy The percentage of patients treated with this dose was twice as high in this group Disarticulation was more often performed in the historical group, whereas amputation was more common in the contemporary group

The differences that could be noted between the two groups with respect to prognostic factors corresponded with the observed differences in metastasis-free rate and survival [illegible] there may be a risk involved in using historical [illegible] when [illegible]

Correlation between prognostic factors and blood variables (IV)

Prognostic factors and blood chemistry were recorded at the time of diagnosis, prior to any treatment, in a consecutive series of 33 patients with primary classical osteosarcoma and scheduled for an 18 month course of adjuvant interferon therapy at the Karolinska Hospital All patients with clinical evidence of metastases on admission were excluded from the series

Analysis of certain blood variables such as haemoglobin, leukocyte and thrombocyte counts albumin, haptoglobin aspartate aminotransferase (Asat), alanine aminotransferase (Alat) and immunoglobulins produced values within the normal range Both the erythrocyte sedimentation rate and the alkaline phosphatase activity were slightly increased, but for this latter blood variable it is very difficult to define reliable normal values for growing individuals

Analysis of prognostic factors showed that one-third of the patients were female, while the average age for the total series was 20 years and the average duration of symptoms 4 months The tumours averaged 10 cm in diameter and in 13 patients were located distally to the knee or elbow The analysis moreover showed a prevalence of osteoblastic high grade tumours

The recorded prognostic factors were subsequently related to each other and to the analyzed blood variables The results of this study show that female patients had a higher incidence of less malignant, more differentiated, fibroblastic tumour types ($p < 0.05$), which are assumed to have a better prognosis A distal tumour site was more common for smaller tumours and was found to have less influence on the recorded blood variables ($p < 0.001$)

Endocrinology

Longitudinal growth and dental development (V)

Between the years 1972–1974 a total of 44 patients (31 males and 13 females) were registered in Sweden under the diagnosis of osteosarcoma without signs of metastatic spread in that time Information on longitudinal growth from birth until the age of diagnosis was obtained from the records of child health centres and school health services where body height is registered at regular intervals These data provided complete growth curves for 19 patients (9 boys and 10 girls)

Analysis of height measurements at 8.0 years when growth is expected to be linear, and at the time of diagnosis – which occurred at a mean age of 13 years for both boys and girls in the series – showed entirely normal growth on comparison with growth curves for other Swedish children at those ages [137] At age 8 a mean height of 128.4 cm was noted for male patients as compared to 128.6 cm for their controls The corre

sponding figures for girls were 129 1 cm and 127 4 cm, respectively A significant correlation was noted between the standardized height at 8 0 years and the standardized height at the age of diagnosis ($r = 0.88$, $p < 0.001$)

A relationship exists between longitudinal growth and tooth eruption [41] Dental maturity was analyzed by a method reported by Filipsson [40] Sufficient data on tooth eruption to permit analysis could be obtained from national and school dental services for 24 patients (16 males and 8 females) Dental development was entirely normal in these osteosarcoma patients, as evidenced by the fact that the mean age noted at the reference point on the tooth eruption curve was 8 67 years for male patients as compared to an age of 8 75 years calculated for controls [40] Mean age for female patients and their normal controls[40] was 8 36 and 8 44 years, respectively

Both longitudinal growth and dental maturity were consequently found to be normal in this analysis of osteosarcoma patients

Glucose tolerance, growth hormone and somatomedin (VI)

A study of glucose tolerance, serum levels of growth hormone and somatomedin, and glucose induced insulin secretion was undertaken in a consecutive series of 15 patients with classical osteosarcoma admitted to the Karolinska Hospital All tests were carried out before any treatment was initiated All patients were in good general condition at the time Both the mean duration of symptoms (3 months) and the age and sex distribution were typical for classical primary osteosarcoma High-grade osteoblastic tumours predominated in the series

Analysis of blood samples showed that somatomedin A and growth hormone levels were entirely within the normal range for age[17,54,55] in all patients at the time of diagnosis This finding is consistent with the normal growth rate observed for osteosarcoma patients in the preceding study (V)

Glucose intolerance has been reported for osteosarcoma patients [53] Glucose infusion tests (GIT)[18] were performed in all 15 patients to study the mechanism underlying the reported glucose intolerance in osteosarcoma No difference in basal glucose and insulin levels was noted between the osteosarcoma patients and healthy controls[32] matched by weight, height and age However, the disappearance rate of glucose[60] (K-value) after glucose infusion was significantly decreased in the patient group This difference was not related to age or sex

A typical biphasic insulin response to the GIT was noted both in the osteosarcoma patients and in the control group There was no difference in initial insulin response between the two groups but during the latter part of the test significantly higher insulin levels were noted for the osteosarcoma patients Decreased glucose tolerance might be explained by reduced insulin sensitivity and analysis of glucose and insulin response to the GIT by means of a mathematical model[19] did in fact demonstrate reduced insulin sensitivity in the osteosarcoma patients

The results of this study showed that somatomedin A and growth hormone levels were within the normal range for age in the osteosarcoma patients The decreased glucose tolerance noted in these patients may be explained by reduced insulin sensitivity

CHAPTER III – GENERAL DISCUSSION

Biopsy and diagnosis

The diagnosis of osteosarcoma may present considerable difficulties even when aided by histologic examination of tumour tissue [28] As a rule a diagnosis of primary classical osteosarcoma will have to be based on the combined evidence provided by the patient's history, the X-rays of both primary tumour and lungs, and histologic analysis of a representative specimen of tumour tissue [14,77,136] The often polymorphous character of the tumour[16,79] urges the need of obtaining specimens from different parts of the neoplastic growth at the time of biopsy [16] For this reason open biopsy is to be preferred, since aspiration or drilling[78,96,135,136] usually fails to provide sufficient material for analysis from different parts of the bone tumour, such as the periosteum, cortex or marrow, and when indicated extra-osseous soft tissue elements

The advisability of obtaining specimens from several portions of the tumour by surgical biopsy prior to definitive surgery has been questioned on the suspicion that manipulation of the tumour might entail a risk of tumour cell embolisation,[34,44,45,95,109,142] which in its turn is suspected to increase the risk of metastasis This theory is supported by animal studies [71,89,143] Although no evidence has been reported of increased metastasis in man,[136] tumour cells have been demonstrated in the blood of patients with malignant tumours subjected to surgery [44,96,134,141]

In our first study (I) we investigated whether open biopsy and a delay between biopsy and definitive surgery had any effect on the long-term prognosis Although small, the series included in this study are comparable to the clinical series reported in connection with studies concerning adjuvant therapy in osteosarcoma in recent years [15] No patient had any signs of metastases at the time of diagnosis and in all cases the tumour was removed by radical surgery, i e amputation or disarticulation of the affected limb

Our study demonstrated no difference in the 5 year survival rate between patients who had an amputation without prior biopsy and those who had a biopsy The survival rate of 21 % noted for both groups is consistent with the 5-year figures reported for large series [27,44,56,76,81,83,86,101,136] Moreover we found no survivors among patients whose definitive surgery was delayed for more than 30 days after biopsy

The radiological and clinical features of benign conditions like osteomyelitis may simulate osteosarcoma and the *necessity of confirming* the diagnosis by open biopsy has in recent years been strongly emphasized [15] Considering the important diagnostic benefits to be gained from open biopsy and the fact that our study failed to demonstrate any negative effect on the long-term prognosis, it would seem that this procedure is to be recommended However, the series will have to be enlarged to permit more reliable conclusions Although the observed difference between the two groups is 0 %, a confidence interval (95 %) of 0±21 % can be calculated

An alternative biopsy procedure involving proximal vascular occlusion by one or two tourniquets and analysis of frozen sections of tumour tissue during operation has been discussed by some authors [27,36,72,80,135,138] However, many pathologists feel that frozen sections are unsatisfactory for a reliable diagnosis of osteosarcoma, since analysis of bone tissue often requires special methods of preparation It has moreover been demonstrated that a proximally applied tourniquet primarily serves to [illegible]
flow but does [illegible]

sponding figures for girls were 129 1 cm and 127 4 cm, respectively A significant correlation was noted between the standardized height at 8 0 years and the standardized height at the age of diagnosis ($r=0\ 88$, $p<0\ 001$)

A relationship exists between longitudinal growth and tooth eruption [41] Dental maturity was analyzed by a method reported by Filipsson [40] Sufficient data on tooth eruption to permit analysis could be obtained from national and school dental services for 24 patients (16 males and 8 females) Dental development was entirely normal in these osteosarcoma patients, as evidenced by the fact that the mean age noted at the reference point on the tooth eruption curve was 8 67 years for male patients as compared to an age of 8 75 years calculated for controls [40] Mean age for female patients and their normal controls[40] was 8 36 and 8 44 years, respectively

Both longitudinal growth and dental maturity were consequently found to be normal in this analysis of osteosarcoma patients

Glucose tolerance, growth hormone and somatomedin (VI)

A study of glucose tolerance, serum levels of growth hormone and somatomedin, and glucose induced insulin secretion was undertaken in a consecutive series of 15 patients with classical osteosarcoma admitted to the Karolinska Hospital All tests were carried out before any treatment was initiated All patients were in good general condition at the time Both the mean duration of symptoms (3 months) and the age and sex distribution were typical for classical primary osteosarcoma High-grade osteoblastic tumours predominated in the series

Analysis of blood samples showed that somatomedin A and growth hormone levels were entirely within the normal range for age[17,54,55] in all patients at the time of diagnosis This finding is consistent with the normal growth rate observed for osteosarcoma patients in the preceding study (V)

Glucose intolerance has been reported for osteosarcoma patients [53] Glucose infusion tests (GIT)[18] were performed in all 15 patients to study the mechanism underlying the reported glucose intolerance in osteosarcoma No difference in basal glucose and insulin levels was noted between the osteosarcoma patients and healthy controls[32] matched by weight, height and age However, the disappearance rate of glucose[60] ("K-value") after glucose infusion was significantly decreased in the patient group This difference was not related to age or sex

A typical biphasic insulin response to the GIT was noted both in the osteosarcoma patients and in the control group There was no difference in initial insulin response between the two groups but during the latter part of the test significantly higher insulin levels were noted for the osteosarcoma patients Decreased glucose tolerance might be explained by reduced insulin sensitivity and analysis of glucose and insulin response to the GIT by means of a mathematical model[19] did in fact demonstrate reduced insulin sensitivity in the osteosarcoma patients

The results of this study showed that somatomedin A and growth hormone levels were within the normal range for age in the osteosarcoma patients The decreased glucose tolerance noted in these patients may be explained by reduced insulin sensitivity

CHAPTER III – GENERAL DISCUSSION

Biopsy and diagnosis

The diagnosis of osteosarcoma may present considerable difficulties even when aided by histologic examination of tumour tissue[28] As a rule a diagnosis of primary classical osteosarcoma will have to be based on the combined evidence provided by the patient's history, the X rays of both primary tumour and lungs, and histologic analysis of a representative specimen of tumour tissue[14,77,136] The often polymorphous character of the tumour[36,79] urges the need of obtaining specimens from different parts of the neoplastic growth at the time of biopsy[14] For this reason open biopsy is to be preferred, since aspiration or drilling[78,96,135,136] usually fails to provide sufficient material for analysis from different parts of the bone tumour, such as the periosteum, cortex or marrow, and when indicated extra-osseous soft tissue elements

The advisability of obtaining specimens from several portions of the tumour by surgical biopsy prior to definitive surgery has been questioned on the suspicion that manipulation of the tumour might entail a risk of tumour cell embolisation,[34,44,45,95,109,142] which in its turn is suspected to increase the risk of metastasis This theory is supported by animal studies[71,89,143] Although no evidence has been reported of increased metastasis in man,[136] tumour cells have been demonstrated in the blood of patients with malignant tumours subjected to surgery[44,96,134,145]

In our first study (I) we investigated whether open biopsy and a delay between biopsy and definitive surgery had any effect on the long term prognosis Although small, the series included in this study are comparable to the clinical series reported in connection with studies concerning adjuvant therapy in osteosarcoma in recent years[15] No patient had any signs of metastases at the time of diagnosis and in all cases the tumour was removed by radical surgery, i e amputation or disarticulation of the affected limb

Our study demonstrated no difference in the 5-year survival rate between patients who had an amputation without prior biopsy and those who had a biopsy The survival rate of 21 % noted for both groups is consistent with the 5-year figures reported for large series.[27,49,56,76,81,83,86,101,136] Moreover we found no survivors among patients whose definitive surgery was delayed for more than 30 days after biopsy

The radiological and clinical features of benign conditions like osteomyelitis may simulate osteosarcoma and the necessity of confirming the diagnosis by open biopsy has in recent years been strongly emphasized[15] Considering the important diagnostic benefits to be gained from open biopsy and the fact that our study failed to demonstrate any negative effect on the long-term prognosis, it would seem that this procedure is to be recommended However, the series will have to be enlarged to permit more reliable conclusions Although the observed difference between the two groups is 0 %, a confidence interval (95 %) of 0±21 % can be calculated

An alternative biopsy procedure involving proximal vascular occlusion by one or two tourniquets and analysis of frozen sections of tumour tissue during operation has been discussed by some authors[27,36,72,80,135,138] However, many pathologists feel that frozen sections are unsatisfactory for a reliable diagnosis of osteosarcoma, since analysis of bone tissue often requires special methods of preparation It has moreover been demonstrated that a proximally applied tourniquet primarily serves to occlude the venous flow but does not prevent intra-osseous circulation, and consequently cannot be claimed to provide a wholly reliable safeguard against tumour cell embolisation[77]

sponding figures for girls were 129 1 cm and 127 4 cm, respectively A significant correlation was noted between the standardized height at 8 0 years and the standardized height at the age of diagnosis ($r = 0\ 88$, $p < 0\ 001$)

A relationship exists between longitudinal growth and tooth eruption [41] Dental maturity was analyzed by a method reported by Filipsson [40] Sufficient data on tooth eruption to permit analysis could be obtained from national and school dental services for 24 patients (16 males and 8 females) Dental development was entirely normal in these osteosarcoma patients, as evidenced by the fact that the mean age noted at the reference point on the tooth eruption curve was 8 67 years for male patients as compared to an age of 8 75 years calculated for controls [40] Mean age for female patients and their normal controls[40] was 8 36 and 8 44 years, respectively

Both longitudinal growth and dental maturity were consequently found to be normal in this analysis of osteosarcoma patients

Glucose tolerance, growth hormone and somatomedin (VI)

A study of glucose tolerance, serum levels of growth hormone and somatomedin, and glucose-induced insulin secretion was undertaken in a consecutive series of 15 patients with classical osteosarcoma admitted to the Karolinska Hospital All tests were carried out before any treatment was initiated All patients were in good general condition at the time Both the mean duration of symptoms (3 months) and the age and sex distribution were typical for classical primary osteosarcoma High-grade osteoblastic tumours predominated in the series

Analysis of blood samples showed that somatomedin A and growth hormone levels were entirely within the normal range for age[17,54,55] in all patients at the time of diagnosis This finding is consistent with the normal growth rate observed for osteosarcoma patients in the preceding study (V)

Glucose intolerance has been reported for osteosarcoma patients [53] Glucose infusion tests (GIT)[18] were performed in all 15 patients to study the mechanism underlying the reported glucose intolerance in osteosarcoma No difference in basal glucose and insulin levels was noted between the osteosarcoma patients and healthy controls[32] matched by weight, height and age However, the disappearance rate of glucose[60] ("K-value ") after glucose infusion was significantly decreased in the patient group This difference was not related to age or sex

A typical biphasic insulin response to the GIT was noted both in the osteosarcoma patients and in the control group There was no difference in initial insulin response between the two groups, but during the latter part of the test significantly higher insulin levels were noted for the osteosarcoma patients Decreased glucose tolerance might be explained by reduced insulin sensitivity and analysis of glucose and insulin response to the GIT by means of a mathematical model[19] did in fact demonstrate reduced insulin sensitivity in the osteosarcoma patients

The results of this study showed that somatomedin A and growth hormone levels were within the normal range for age in the osteosarcoma patients The decreased glucose tolerance noted in these patients may be explained by reduced insulin sensitivity

for patients treated *only* by conventional methods like surgery and irradiation in comparison with earlier series of similarly treated patients [8,138] In this context the selection of patients was discussed, since patients with a presumably better prognosis might be more liable to be admitted to one centre than to another [8,42,81] Another question raised was whether refined radiological diagnostic techniques including lung tomography and scintigraphy might contribute to the exclusion of patients with metastatic spread at the time of diagnosis, implying a poorer prognosis [138] The higher survival rate in patients with lung metastases could to some extent be explained by the more active approach adopted in the treatment of such metastases All this has cast doubt on the reliability of historical controls

In the study undertaken at the Karolinska Hospital of adjuvant interferon treatment in patients with classical osteosarcoma without evidence of metastatic spread, we used a historical control group of 35 patients treated at this hospital between 1952 and 1972 To make evaluation of the effect of interferon treatment more reliable and to reduce the risk of selecting patients characterized by factors tending to influence prognosis in a positive or negative way, we collected all patients in Sweden who during the years 1972–1974 received a diagnosis of classical primary osteosarcoma without evidence of metastatic spread at that time and who did not receive adjuvant therapy Together with the patients treated with interferon during the same period, this produced a contemporary group of 44 patients A comparative analysis of a number of prognostic factors disclosed appreciable differences between the historical and the contemporary group

Sex

It has earlier been suggested that female osteosarcoma patients have a better prognosis[45,80,102 106 119,138] and the question has been raised whether this might be related to the female sex hormone, estrogen [84,120] In large series of primary osteosarcoma the proportion of females is usually reported as one-third [26] In our study of prognostic factors (II) the histor [illegible] longer duration of symptoms for female patients and a higher incidence of less malignant, i e low-grade fibroblastic tumours than among the males Moreover it may be noted that two-thirds of the 12 patients surviving without tumour recurrence at the 5-year follow-up in our study on biopsy and survival (I) were female, whereas the sex distribution was reversed in the original series of 57 patients

Age

One of the criter [illegible] coma is that it a [illegible] rial includes 3 [illegible] group and 4 in the contemporary group who were over 30, but otherwise manifested a clinical picture wholly typical of primary osteosarcoma In some earlier studies a more favourable prognosis for older patients has been discussed [27,60,83,101] *In our study correlating prognostic factors and blood variables* (IV) we noted that the duration of symptoms increased with age, which might be ascribed to slower tumour growth in older patients No correlation was found between age and tumour pathology, size or location

Surgery

Authors discussing the level of amputation seem to be agreed that tumours located distally to the elbow or knee should be removed by transmedullary amputation of the proximal part of the limb, i e the thigh or upper arm [36,135] Concerning the most common tumour site, the distal femur, opinions are more divided *Some authors feel that this* tumour site demands disarticulation at the hip joint whereas others recommend proximal femoral amputation [14,27,36,63,76,86,134] Underlying the demand for extreme radicality are some reports demonstrating the occurrence of so-called "skip lesions", that is, neoplastic foci at a different site from the primary tumour but within the same limb, usually in the same long bone but occasionally with a transarticular location [14,35,37] Although these findings have been called in question,[29,66,78] the intramedullary encroachment observed in amputation specimens in some cases suggests that this may be more extensive than can be visualized by the preoperative X-rays [134,146] Bone scans and tomography have regrettably proved to be of limited value as an additional aid in the preoperative assessment of tumour growth [36,52,134] Angiography is primarily useful in demonstrating extraosseous tumor growth [36,73,134,150]

The introduction in recent years of adjuvant therapy, which is believed to have an effect on micrometastasis, has led many surgeons to revise their views on amputation surgery and en bloc resection of the tumour has been frequently adopted instead [1,65,85,93,110] This implies removal of the tumour with a smaller safe margin, often allowing preservation of an adequately functioning limb The defect left by the tumour is replaced *either by foreign implants such as plastic or metal prostheses or by autologous tissue such* as bone grafts [93]

If local resection is to satisfy the demand for complete radicality, it will be necessary to extirpate the site of any previous biopsy incision in one single piece with the rest of the tumour *This places additional demands on an adequate biopsy technique including* selection of the right site for incision and caution in manipulating tumour tissue [80 93 135] The same surgeon will often be required to perform both biopsy and definitive surgery

At the Karolinska Hospital adjuvant therapy with human leukocyte interferon was introduced in 1971 and so far a consecutive series of 42 osteosarcoma patients without radiological evidence of metastases has been treated Fifteen of these 42 patients were operated upon with local resection of the tumour following open biopsy [93] Six of these patients have so far been followed up for at least five years and four are alive without evidence of tumour recurrence, while two have died from other causes

Prognostic factors

Prior to the 1970's the survival rate for osteosarcoma patients was low often less than 20 % after a 5-year follow-up [27 49,56 77 80 81 83 86 97 135] *In 1972 the first report on* the positive results of chemotherapy (methotrexate adriamycin) in metastatic osteosarcoma were published,[23 62] followed by the introduction of systematic treatment by various cytostatics as adjuvant therapy in patients with osteosarcoma without evidence of metastatic spread *at the time of diagnosis* Early reports showed promising results but were based on small series and short observation periods [24 64 128] With longer observation periods the results were somewhat less favourable and today combined treatment with different drugs, often administered in maximum doses yields a 5-year survival rate of 40–50 % [25,38 48,57 66 69,99,112 133]

Around 1976 the question was raised whether the natural history of osteosarcoma might be changing since some centres in recent years had noted higher survival rates

for patients treated only by conventional methods like surgery and irradiation in comparison with earlier series of similarly treated patients[8,138] In this context the selection of patients was discussed, since patients with a presumably better prognosis might be more liable to be admitted to one centre than to another[8,42,81] Another question raised was whether refined radiological diagnostic techniques including lung tomography and scintigraphy might contribute to the exclusion of patients with metastatic spread at the time of diagnosis, implying a poorer prognosis[138] The higher survival rate in patients with lung metastases could to some extent be explained by the more active approach adopted in the treatment of such metastases All this has cast doubt on the reliability of historical controls

In the study undertaken at the Karolinska Hospital of adjuvant interferon treatment in patients with classical osteosarcoma without evidence of metastatic spread, we used a historical control group of 35 patients treated at this hospital between 1952 and 1972 To make evaluation of the effect of interferon treatment more reliable and to reduce the risk of selecting patients characterized by factors tending to influence prognosis in a positive or negative way, we collected all patients in Sweden who during the years 1972–1974 received a diagnosis of classical primary osteosarcoma without evidence of metastatic spread at that time and who did not receive adjuvant therapy Together with the patients treated with interferon during the same period, this produced a contemporary group of 44 patients A comparative analysis of a number of prognostic factors disclosed appreciable differences between the historical and the contemporary group

Sex

It has earlier been suggested that female osteosarcoma patients have a better prognosis[43,80,102,106,119,138] and the question has been raised whether this might be related to the female sex hormone, estrogen[84,120] In large series of primary osteosarcoma the proportion of females is usually reported as one-third[26] In our study of prognostic factors (II) the historical group included slightly more female patients than expected, while the ratio between females and males in our study on metastases and survival (III) was 1 2 In our analysis of prognostic factors and blood variables (IV) we found a longer duration of symptoms for female patients and a higher incidence of less malignant, i e low-grade fibroblastic tumours than among the males Moreover it may be noted that two-thirds of the 12 patients surviving without tumour recurrence at the 5 year follow-up in our study on biopsy and survival (I) were female, whereas the sex distribution was reversed in the original series of 57 patients

Age

One of the criteria commonly [illegible]
coma is that it affects patients [illegible]
rial includes 3 patients in the [illegible]
[illegible] in the contemporary group who
were over 30, but otherwise manifested a clinical picture wholly typical of [illegible]
sarcoma In some earlier [illegible]
discussed[27,80,83,101] [illegible]
(IV) we noted that the du[illegible]
[illegible] with age, which might be ascribed
to slower tumour growth in older patients No correlation was found between age and tumour pathology, size or location

Type and duration of symptoms

Pain is the most common symptom, followed by swelling[26,81,83,136] Pathological fracture of the involved bone was noted in a few cases, but generally no prognostic importance has been attached to this in the literature[81] The incidence of symptoms was higher in the historical than in the contemporary group but their duration, which is reported to be correlated to prognosis,[28,81,83,118] was the same in both groups The more favourable prognosis associated with a longer duration of symptoms may be ascribed to a better individual reaction to the tumour resulting in slower tumour growth[81,125] This assumption would also seem to be consistent with the positive correlation observed in our study on prognostic factors and blood variables (IV) between duration of symptoms and low-grade tumours as well as higher serum levels of immunoglobulin G

Size and location of tumour

In our study on prognostic factors and survival (III) we found that tumour size, as measured by the greatest diameter on the X-rays on the average was twice as large in the historical group as in the contemporary group A significant difference in tumour size between these two groups was also observed in our analysis of prognostic factors (II) which yielded a tumour size exceeding 10 cm in 64 % of the patients in the historical group A considerably poorer prognosis has been reported for tumours exceeding 10 cm in diameter[81,83,118,136] In addition, our study on prognostic factors and blood variables (IV) disclosed a correlation between tumour size and its location, since we found distal tumours to be smaller They were also associated with higher levels of haemoglobin and albumin, a lower erythrocyte sedimentation rate and a lower haptoglobin serum level Although it should also be easier to recognize distally located tumours at an earlier stage this study (IV) failed to demonstrate a positive correlation between tumour size and duration of symptoms Similarly, there was no correlation between tumour size and tumour pathology

The prognostic significance of tumour location has been a subject of discussion in the literature Some authors consider distal location a favourable sign,[27,29 49,75 81 147,148] whereas others fail to establish such a relationship[80,83 102 118,119 136] Although the difference was statistically not significant, the historical group contained a greater number of proximally located tumours

Tumour pathology

Several authors classify osteosarcoma according to the dominant cell type in an osteoblastic, chondroblastic and fibroblastic variety[28 36 102] The value of this classification however, has been called in question[80 81 101 136] We have mentioned earlier that it is important to base histological examination on serial sections since different parts of the tumour may present varying features[26 36] Some authors feel that the chondroblastic type is associated with the poorest prognosis[101 119] whereas Dahlin s studies identify the osteoblastic type as the most malignant form of osteosarcoma[27 28]

A predominance of osteoblastic Grade IV tumours was found in the historical group and this group totally included significantly more Grade IV tumours Earlier reports have questioned the value of malignancy grading on the basis of tumour cell differentiation[27, 81, [redacted] 101, 136 141, 148] The literature provides no information to suggest a better prognosis for fibroblastic tumours, but our correlation study (IV) demonstrated that this type was more common in low grade tumours and had a higher incidence among female

patients Ten of the 33 patients included in this study were followed up for 5 years and 5 of them survived without signs of tumour recurrence Four of these 5 patients (80 %) had a fibroblastic tumour as compared to 8 of the 33 patients (24 %) in the original series All 33 patients received adjuvant interferon therapy for an equally long period The presence of osteoid in the tumour tissue could be clearly demonstrated and histologically the tumours could be clearly differentiated from fibrosarcoma

The historical group consequently showed a higher incidence of large sized proximally located and high-grade osteoblastic tumours than the contemporary group Such factors are assumed to be indicative of a poorer prognosis This was investigated in our study on metastases and survival (III) in which patients who had received adjuvant interferon therapy were excluded from the contemporary group A comparison between the two new groups showed that the differences with respect to prognostic factors persisted

A clear difference could be noted both in the incidence of metastases and in the survival rate after 2 5 years follow-up At this point of time the incidence of patients without metastases was twice as high in the contemporary group and the same relation was observed with respect to the number of survivors In an attempt to explain these differences we also studied the methods of treatment adopted in the two groups

Treatment

Radiation therapy For decades the treatment of primary osteosarcoma has consisted in surgery or irradiation or a combination of both[49] The extremely low 5 year survival rate observed in patients treated only by surgery led Cade[13 14] to introduce treatment of primary tumours with preoperative irradiation in high doses of 60–90 Gy followed by a 6-month period of observation prior to definitive surgery This was intended to avoid surgery for those patients who developed metastases during the 6 month interval Micrometastases are assumed to be present in a majority of patients – according to some authors up to 80 % – at the time of diagnosis Studies of large series have shown that lung metastases can be radiologically verified in more than half of the patients within 6 months of diagnosis[15 38 86 115 136]

the 5 year survival rate for patients treated by irradiation only is in many studies reported as lower than that resulting from surgical treatment only Some studies report no better results from a combination of surgery and irradiation[21 36 49 60 83 118 136] but it may be suspected that these findings are biased by the selection of patients not suited for surgical treatment

With the introduction of adjuvant therapy which is most effective when there is limited tumour involvement and the primary tumour is removed at an early stage preoperative radiation therapy has been virtually discarded and the treatment is today primarily used as a palliative procedure for inoperable tumours[21] Cade claimed that high radiation doses were required to achieve antitumoral effects[14] In the contemporary control group radiation therapy with doses exceeding 45 Gy was given to twice as many patients as in the historical group A comparable number of patients in either group was scheduled for a 6-month observation period on conclusion of irradiation before surgical treatment was to be initiated These patients are included in the study Two patients in the contemporary group and 5 in the historical group developed metastases during this 6 month interval and had no surgery This should not influence a prognostic comparison

Type and duration of symptoms

Pain is the most common symptom, followed by swelling[26,81,83,136] Pathological fracture of the involved bone was noted in a few cases, but generally no prognostic importance has been attached to this in the literature[81] The incidence of symptoms was higher in the historical than in the contemporary group but their duration, which is reported to be correlated to prognosis,[28,81,83,118] was the same in both groups The more favourable prognosis associated with a longer duration of symptoms may be ascribed to a better individual reaction to the tumour resulting in slower tumour growth[81,125] This assumption would also seem to be consistent with the positive correlation observed in our study on prognostic factors and blood variables (IV) between duration of symptoms and low-grade tumours as well as higher serum levels of immunoglobulin G

Size and location of tumour

In our study on prognostic factors and survival (III) we found that tumour size, as measured by the greatest diameter on the X-rays, on the average was twice as large in the historical group as in the contemporary group A significant difference in tumour size between these two groups was also observed in our analysis of prognostic factors (II), which yielded a tumour size exceeding 10 cm in 64 % of the patients in the historical group A considerably poorer prognosis has been reported for tumours exceeding 10 cm in diameter[81,83,118,136] In addition, our study on prognostic factors and blood variables (IV) disclosed a correlation between tumour size and its location, since we found distal tumours to be smaller They were also associated with higher levels of haemoglobin and albumin, a lower erythrocyte sedimentation rate and a lower haptoglobin serum level Although it should also be easier to recognize distally located tumours at an earlier stage this study (IV) failed to demonstrate a positive correlation between tumour size and duration of symptoms Similarly, there was no correlation between tumour size and tumour pathology

The prognostic significance of tumour location has been a subject of discussion in the literature Some authors consider distal location a favourable sign[27 29 49,75 81 147,148] whereas others fail to establish such a relationship[80,83,102,118,119,136] Although the difference was statistically not significant, the historical group contained a greater number of proximally located tumours

Tumour pathology

Several authors classify osteosarcoma according to the dominant cell type in an osteoblastic, chondroblastic and fibroblastic variety[28,36 102] The value of this classification however, has been called in question[80 81 101 136] We have mentioned earlier that it is important to base histological examination on serial sections since different parts of the tumour may present varying features[26 36] Some authors feel that the chondroblastic type is associated with the poorest prognosis[101 119] whereas Dahlin s studies identify *the osteoblastic type* as the most malignant form of osteosarcoma[27,28]

A predominance of osteoblastic Grade IV tumours was found in the historical group and this group totally included significantly more Grade IV tumours Earlier reports have questioned the value of malignancy grading on the basis of tumour cell differentiation[27,81,83,101,136 141,148] The literature provides no information to suggest a better prognosis for fibroblastic tumours, but our correlation study (IV) demonstrated that this type was *more common* in low-grade tumours and had a higher incidence among female

counteract this microscopic tumour spread have been suggested [5,48] During the 1970's various cytostatics have been introduced as adjuvant therapy [15] Following initial reports of highly successful results, various centres throughout the world have subsequently reported results based on larger series and longer follow-up periods providing an average survival rate of about 50 %, but the results of different centres vary widely [15] Treatment with a combination of different cytostatics – primarily adriamycin and methotrexate – in doses frequently approaching the maximum dose has been associated with severe side-effects Even lethal effects have been reported [88]

Attempts have also been made to treat osteosarcoma patients with anticoagulants, transfer factor and various other regimens of immunological therapy [11,22,33,51,58,112,114] As a rule such treatment is recommended only as a supplement to radical surgery and adjuvant chemotherapy In many cases adjuvant therapy of different kinds is founded on in vitro and animal experiments, [16,47,48,126,127] and some authors have succinctly described the state of adjuvant therapy in osteosarcoma today as presenting "more questions than answers" [90]

To summarize, our comparison of prognostic factors in a historical and a contemporary group in several studies (II–IV) has demonstrated a number of differences between the two groups (Table II)

Table II Difference in prognostic factors between the historical and the contemporary group

Prognostic factors	Historical versus contemporary group
Symptoms	Higher incidence
Tumour size	Larger
Tumour pathology	Higher incidence of osteoblastic and Grade IV tumours
Radiation therapy	Lower incidence
Surgery	Higher incidence of disarticulation
Treatment of pulmonary metastases	Less active (no surgery or high-dose chemo therapy)

The historical group features a higher incidence of unfavourable prognostic factors such as a proximal tumour location larger and more malignant tumours In addition a more aggressive approach to the treatment of metastases presumably resulting in increased survival was noted in the contemporary group Up to-date curves for the [illegible]

[illegible] risk, however, in evaluating the effect of adjuvant therapy by comparison of small clinical series with a short follow-up An analysis of prognostic factors in the series to be compared is imperative especially in non-randomized studies

since both groups originally included an equal number of patients scheduled for this form of treatment

Prophylactic irradiation of the lungs to destroy micrometastases has been tested in prospective randomized studies without providing a conclusive answer [7,12,105] No patient in any of the groups included in the present study has received such adjuvant treatment

Surgery Disarticulation was considerably more common among patients in the historical than in the contemporary group This operation was performed in almost half of the patients in the historical group, partly because of a higher incidence of proximally located tumours and probably partly owing to the prevailing opinion of the day that disarticulation was necessary to ensure radicality This will scarcely influence a prognostic analysis however, since macroscopically radical removal of the tumour was carried out in all patients subjected to surgery

Treatment of lung metastases Metastasis of osteosarcoma is hematogenous and predominantly involves the lungs [14,26,61,67,79] In spite of the fact that the average duration of symptoms is less than 6 months it is assumed that the majority of patients[14] – probably up to 80 % – have lung metastases at the time of diagnosis [8,27,56,64 77] Prior to the 1970's the approach towards treatment of lung metastases was highly conservative and as a rule any treatment given was purely palliative

The reports claiming successful results with methotrexate or adriamycin therapy for macroscopic metastases in osteosarcoma marked the beginning of a more aggressive approach to the treatment of such metastases Optimal antitumoral effect was observed when there was limited tumour involvement [36,48,56,110] Adjuvant therapy has also produced a somewhat changed course of the disease in that fewer and often solitary metastases have been noted to occur and sometimes at a later stage [4 10,63,98,99 130] As a consequence surgical removal of lung metastases by lobe resection lobectomy and sometimes total pulmectory seemed more justified and in recent years promising results have been reported of such surgery [3 12,59,87,111,113,121,124,140]

That a similar change in attitude with respect to the treatment of lung metastases had taken place in Sweden was evident from our study comparing the historical and contemporary groups in this respect (III) In almost half of the patients in the contemporary group who developed lung metastases these were removed by surgery while 25 % of these patients received high-dose chemotherapy No patient in the historical group had pulmonary surgery, while high-dose chemotherapy was not available at the time The difference in the two groups with respect to the treatment of lung metastases to some extent serves to explain the difference in the survival rates noted at the 2 5 year follow-up Whether active treatment of lung metastases delays the plateau phase in the survival curve cannot be definitely concluded from our study after 2 5 years follow-up According to earlier studies lung metastases were noted in 80 % of the patients within one year and since all patients in our study had been followed up for at least 2 5 years this was the time selected for comparison of the two groups A combination of adjuvant therapy and active treatment of lung metastases might be expected to produce a further delay of the plateau phase in the curves expressing metastasis-free and survival rates and thus urge the need for an increased follow-up period

Adjuvant therapy Dissemination of the tumour prior to diagnosis and initial treatment is considered of crucial importance for prognosis and various forms of treatment to

... [5,48] During the 1970 s ... following initial reports ... orld have subsequently reported results based on larger series and longer follow-up periods providing an average survival rate of about 50 %, but the results of different centres vary widely [15] Treatment with a combination of different cytostatics – primarily adriamycin and methotrexate – in doses frequently approaching the maximum dose has been associated with severe side-effects Even lethal effects have been reported [III]

Attempts have also been made to treat osteosarcoma patients with anticoagulants, transfer factor and various other regimens of immunological therapy [11,22,33,51,58,112,114] As a rule such treatment is recommended only as a supplement to radical surgery and adjuvant chemotherapy In many cases adjuvant therapy of different kinds is founded on in vitro and animal experiments [16,47,48,126,127] and some authors have succinctly described the state of adjuvant therapy in osteosarcoma today as presenting "more questions than answers" [90]

To summarize, our comparison of prognostic factors in a historical and a contemporary group in several studies (II–IV) has demonstrated a number of differences between the two groups (Table II)

Endocrinology

Growth

Osteosarcoma is most common in young individuals and its incidence is almost twice as high among males, with a peak usually coinciding with the pubertal growth spurt[27,74,81,100,119,147] It has been suggested that both pathogenesis and prognosis are influenced by hormonal factors[53] Female patients are claimed to have a better prognosis[45,80,102,106,138] and in vitro studies have demonstrated estrogen to have a positive antitumoral effect[120] The predominant site of the tumour is the metaphyseal region of the long bones and in the majority of patients the tumour is located in the region of the knee[27,36]

Earlier studies have reported a predominance of tall individuals,[21,46,74,100,120] but no analysis has been performed to determine whether osteosarcoma is associated with an abnormal rate of growth Such an analysis has been attempted in our study of individual growth curves of osteosarcoma patients (V) In contrast to the earlier studies, which were based on cross-sectional growth data instead of individual growth curves, our analysis failed to demonstrate any deviations in longitudinal growth A relationship exists between longitudinal growth and tooth eruption[41] In our analysis dental maturity was found to be normal and consequently supported our findings regarding normal growth in osteosarcoma patients The average duration of symptoms, reported as 3–10 months in earlier studies,[49,81,136] was 3 months for the patients in this study The possibility of the tumour itself stimulating growth could therefore not be excluded, since the period from the presumed onset of the disease until diagnosis was too short to allow detection of growth rate increment The sex distribution in this study was not wholly typical for osteosarcoma patients The proportion of female patients was larger than might be expected, but since comparisons were made within each sex this could not influence the results

Additional evidence to support our finding of normal growth in osteosarcoma patients was provided by a subsequent study (VI), which showed serum levels of somatomedin A and growth hormone to be within the normal range for age for these patients Earlier studies reporting increased levels of these hormones may have failed to take sufficient account of variations in age, especially with respect to somatomedin levels

Glucose tolerance

A high incidence of diabetes mellitus has been reported for tumour patients[70] Glucose intolerance may be ascribed to stress and malnutrition factors in cancer patients in poor general condition[31,149] Glucose homeostasis may also be influenced by polypeptide hormone secretion by the tumour tissue[108] Earlier studies have reported glucose in tolerance in osteosarcoma patients in combination with hyperinsulemia[53] In our study (VI) glucose tolerance was analyzed in 15 osteosarcoma patients This study provided evidence of glucose intolerance, consistent with earlier reports, and showed that this could most likely be ascribed to decreased peripheral insulin sensitivity At present we can only speculate whether this decreased sensitivity should be attributed to hormones or hormone homologues secreted by the tumour tissue In order to analyze this, glucose infusion tests were performed in several patients after removal of the tumour and no change in glucose tolerance or insulin sensitivity was noted in these cases (Unpublished observations)

There was considerable individual variation in insulin sensitivity, but all patients manifesting extremely low insulin sensitivity developed metastases The follow-up period

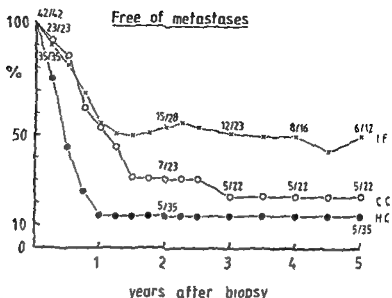

Fig 1 Up-to date metastasis-free rate in interferon-treated patients (x—x, N=42) con temporary control group (o—o, N=23) and historical control group (●—●, N=35)

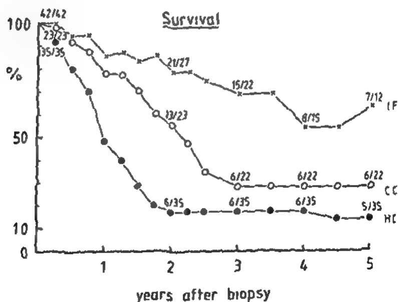

Fig 2 Up-to-date survival rate in interferon treated patients (x—x N=42) contempo rary control group (o—o N=23) and historical control group (●—●) N=35)

CHAPTER 4 – GENERAL SUMMARY AND CONCLUSIONS

The present study permits the following observations and conclusions

1 Open biopsy is advisable in the diagnosis of osteosarcoma in view of the many advantages offered by this procedure and the fact that no negative effect on long term survival was demonstrated On the other hand too long a delay between biopsy and definitive surgery would not seem to be advisable

2 Comparison between a historical and a contemporary group demonstrated a pre dominance of unfavourable prognostic factors in the historical group This group was characterized by a higher incidence of symptoms larger and histologically more malignant tumours and a higher incidence of proximally located tumours

3 A contemporary and a historical group without adjuvant tumour treatment mani fested clear differences with respect to the incidence of metastases and the sur vival rate after 2 5 years follow up The percentage of survivors and patients with out metastases was twice as high in the contemporary group at this time The in creased survival rate for patients with lung metastases in the contemporary group could partly be ascribed to the more aggressive approach adopted in the treatment of such metastases

4 Evaluation of the effect of any therapy in non randomized studies requires an analysis of prognostic factors to disclose possible differences between the clinical series There would seem to be a definite risk in using historical controls in such studies based on small series with a short period of observation

5 The blood variables studied in osteosarcoma patients provided values within the normal range with the exception of the erythrocyte sedimentation rate

6 Correlation analysis disclosed that female patients had a higher incidence of low grade tumours and that a distal tumour site was more common in tumours of smaller size

7 Normal longitudinal growth and normal dental development were found in osteo sarcoma patients This finding is supported by the results of our study demon strating normal serum levels of somatomedin A and growth hormone

8 Decreased glucose tolerance was demonstrated in our osteosarcoma patients and could most likely be attributed to decreased insulin sensitivity

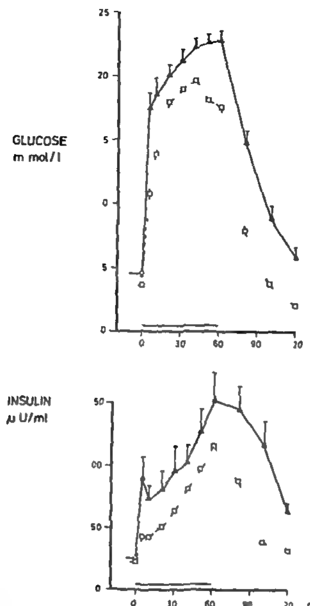

Fig 3 Glucose and insulin levels during GIT in single patient free of metastases after 3 5 years (□ — □) and 8 patients with metastases within one year (▲ — ▲ vertical bars indicate SEM)

varies for the patients included in this consecutive series but the patient without metastases after the longest follow up (3 5 years) belonged to the group manifesting normal insulin sensitivity Insulin and glucose response to the glucose infusion test for this patient as compared to the 8 patients who developed metastases within one year (Fig 3) showed a tendency to lower serum glucose levels during the test and a more rapid decline of the serum glucose level on conclusion of the test Both the insulin level and the calculated K value were within the normal range for this patient whereas K values were significantly decreased for the patient group as a whole

Whether insulin sensitivity may be useful as a prognostic factor in osteosarcoma will be investigated in further studies based on a larger number of patients with a sufficiently long follow up to permit more reliable prediction of the long term outcome

CHAPTER 4 – GENERAL SUMMARY AND CONCLUSIONS

The present study permits the following observations and conclusions

1 Open biopsy is advisable in the diagnosis of osteosarcoma in view of the many advantages offered by this procedure and the fact that no negative effect on long-term survival was demonstrated On the other hand, too long a delay between biopsy and definitive surgery would not seem to be advisable

2 Comparison between a historical and a contemporary group demonstrated a predominance of unfavourable prognostic factors in the historical group This group was characterized by a higher incidence of symptoms larger and histologically more malignant tumours, and a higher incidence of proximally located tumours

3 A contemporary and a historical group without adjuvant tumour treatment manifested clear differences with respect to the incidence of metastases and the survival rate after 2 5 years' follow-up The percentage of survivors and patients without metastases was twice as high in the contemporary group at this time The increased survival rate for patients with lung metastases in the contemporary group could partly be ascribed to the more aggressive approach adopted in the treatment of such metastases

4 Evaluation of the effect of any therapy in non-randomized studies requires an analysis of prognostic factors to disclose possible differences between the clinical series There would seem to be a definite risk in using historical controls in such studies based on small series with a short period of observation

5 The blood variables studied in osteosarcoma patients provided values within the normal range with the exception of the erythrocyte sedimentation rate

6 Correlation analysis disclosed that female patients had a higher incidence of low-grade tumours and that a distal tumour site was more common in tumours of smaller size

7 Normal longitudinal growth and normal dental development were found in osteosarcoma patients This finding is supported by the results of our study demonstrating normal serum levels of somatomedin A and growth hormone

8 Decreased glucose tolerance was demonstrated in our osteosarcoma patients and could most likely be attributed to decreased insulin sensitivity

ACKNOWLEDGEMENTS

The people who have assisted me directly or indirectly in the preparation of this book are too numerous to thank them all individually To some of them, however, I owe a special debt of gratitude which I wish to acknowledge here

Professor Sven Olerud, Head of the Department of Orthopaedic Surgery, Karolinska Hospital, has been equally generous in providing excellent working facilities and in encouraging my work by his friendly interest and positive criticism

Associate Professor Ulf Nilsonne, Head of the Section of Orthopaedic Oncology, Department of Orthopaedic Surgery, Karolinska Hospital, introduced me to orthopaedic oncology and first awakened my interest in the problem of osteosarcoma Throughout the progress of this work I have benefited from his continuous and enthusiastic interest, his stimulating discussions and the personal friendship he has shown me

Professor Jerzy Einhorn, Head of Radiumhemmet, Karolinska Hospital, allowed me to use the facilities of his Department and has devoted much time and generous effort to reading manuscripts and offering discerning criticisms and suggestions

Associate Professor Hans Strander, Radiumhemmet, Karolinska Hospital, has shared the progress and the problems of this work from its very beginning His friendship and generosity have found many ways of expression, not least of which is the unstinting way in which he has given of his time and knowledge to guide my steps and share his wide experience in the field of oncologic research and as an author

Dr Snorri Ingimarsson, Radiumhemmet, Karolinska Hospital, has been a staunch friend and spent countless hours in discussing my work, offering constructive criticism and suggesting new lines of endeavour His unfailing practical and moral support has been invaluable to me

Professor Kari Cantell, Central Public Health Laboratory, Helsinki, Finland, has been very kind in discussing the use of interferon in the treatment of osteosarcoma

Associate Professors Kerstin Hall and Ulf Adamson, Department of Endocrinology, Karolinska Hospital, instructed me in the fundamentals of their speciality Their guidance, advice and stimulating cooperation and their reading and criticism of the manuscripts dealing with endocrinological aspects have done much to enhance the cogency of this part of the work

Professor Gunnar Eklund, Nordic School of Public Health Gothenburg not only gave me the benefit of his expert statistical advice but also contributed numerous valuable suggestions on the planning and evaluation of parts of the investigation

Dr Gosta Enberg, Department of Endocrinology and Mr Leif Karnstrom, Radiumhemmet, Karolinska Hospital, assisted with the statistical calculations

This work naturally owes a large debt of gratitude to the co-authors who contributed their knowledge to the papers on which this review is based In addition to the persons mentioned above, they were Dr Daniel R Cooperman Dr Mariel A Harris and Dr Michael A Simon, Department of Surgery, Section of Orthopaedic Surgery University of Chicago Hospitals and Clinics, Assistant Professor Tomas Aparisi Department of Orthopaedic Surgery, Associate Professor Suad Efendic, Department of Endocrinology Associate Professor Curt Lagergren Department of Diagnostic Radiology Radiumhemmet, and Assistant Professor Gunnar Soderberg Department of Tumour Pathology Karolinska Hospital, Associate Professor Rune Filipsson Department of Clinical Genetics Karolinska Institute

Ms Catherine Sundstrom, Department of Orthopaedic Surgery Karolinska Hospital translated this review into English Her astute advice and indefatigable zeal in preparing the manuscript for publication have been a tremendous help

Mr Victor Braxton has revised the English text of Papers II–IV.

Mrs Ingrid Lettstrom, Department of Orthopaedic Surgery, Karolinska Institute, has shown great forbearance in typing and re-typing manuscripts and checking references She has handled the financial administration of the project and lightened my task by taking care of numerous practical details

Mrs Rigmor Almung, Department of Orthopaedic Surgery, Karolinska Hospital, has expedited the collection of material by her unfailing readiness to procure the patient records needed for this investigation

Mrs Annelie Nyberg, Department of Endocrinology, has provided excellent technical assistance

Mrs Margareta Lindborg and the secretarial staff at Radiumhemmet have helped with the typing and the financial administration

Colleagues and staff at the Department of Orthopaedic Surgery have been patient with me

The loyal support and cheerful understanding of my wife Ulla Britt and our two daughters offering a constant refuge from the labours of this task, have been vital to its completion

The work was supported by grants from the Swedish Cancer Society, the Cancer Society of Stockholm, the Anders Otto Sward foundation, the Swedish Medical Research Council 4224, the Swedish Society of Medical Sciences, and the Karolinska Institute's funds

1 INTRODUCTION

Primary malignant bone tumours have been known for thousands of years Archaeological research shows that the Egyptians were familiar with them already at the time of the building of the pyramids (see Christensen, 1925 Ott et al 1977) The study and diagnosis of bone tumours has continued right up to our own time As far as one can tell from the literature on the subject, the first person to describe a primary malignant bone tumour was Dalrymple, who, in 1846, diagnosed myeloma nodules or *mollities ossium* (see Carson et al 1955) Bence-Jones discovered that the urine of myeloma patients secreted thermolabile albumin The clinical details of myeloma were described by McIntyre in 1850 (see Lumb et al 1948) Virchof diagnosed chordoma in 1857 (see Spjut et al 1964) and in 1922 Beck observed the carcinogenic effect on bone of ionising radiation In the same year James Ewing published a study of diffuse endothelioma of the bone a disease that differed from both osteo-sarcoma and myeloma and which is now known as Ewing s sarcoma In 1928 and 1930 respectively Oberling discovered reticulum cell sarcoma and Phemister, chondro-sarcoma diseases that now bear their names In 1943 Budd and MacDonald diagnosed fibro-sarcoma Parosteal osteo-sarcoma was discovered in 1951 (Gesichcter and Copeland) and lipo-sarcoma in 1955 (Dawson) Primary malignant fibrous histio-cytoma of the bone was first mentioned in 1975 (Spanier et al)

Primary malignant bone tumours have been a constant object of scientific study As a result of developments in surgery, new techniques like extensive bone transplants and bio-mechanical prostheses have made it possible to treat patients without disabling them to the same extent as heretofore Developing radiation treatment and in recent years particularly cytostat treatment as well as immunological treatment which is still at the experimental stage have provided new possibilities for helping patients with bone tumours

In Finland, primary malignant bone tumours have been studied by the follow-

ing investigators among others. F. Langenskiold (1929), Mustakallio (1937, 1947), Roukkula (1959), Tala and Koikkalainen mio (1969), Koskinen (1967, 1968, 1972, 1973, 1978, 1979) and Paavolainen and Teppo (1976)

2. SURVEY OF LITERATURE

2.1 INCIDENCE

According to the information provided by cancer registries in different countries primary malignant bone tumours are rare. They account for approximately two per cent of all malignant tumours in man. Since the weight of the human skeleton is about 20 % of the whole body (Rauber-Kopsch 1958) it might be expected that there would be a higher frequency of bone tumours. The 10^5 incidence rate per inhabitant varies in different countries from 0.7 to 4.0 (Hoppe et al. 1952, The Swedish Cancer Registry 1960, The Cancer Registry of Norway 1964, Copeland 1967, Robertsson et al. 1967, Boyd et al. 1969, Bristol Bone Tumour Registry 1971, Teppo et al. 1972, Ott et al. 1977). The lack of national registries outside Scandinavia makes it difficult to get precise information.

The occurrence of malignant bone tumours may vary geographically within the same country. Thus in South Africa, bone tumours and connective-tissue tumours are less common in the Johannesburg region than elsewhere (Robertson et al. 1967). Paget's disease and the bone sarcoma that results from it are common in Great Britain, but rare in Norway, Greece, Japan and the United States (Price et al. 1962, Lochkin et al. 1963). Paget's disease is most widespread in Great Britain (Price et al. 1962).

2.2 HISTO-PATHOLOGICAL CLASSIFICATION

The present histo-pathological classification of bone tumours is the outcome of prolonged research. The classification published by the World Health Organization (Schajowicz et al.) in 1972 is based on clinical, radiological and histo-pathological research. Table 2.

Table 2. Histological classification of primary malignant bone tumours (Schajowicz et al. WHO, 1972)

Bone-forming tumours
Osteo-sarcoma
Parosteal osteo-sarcoma
Cartilage-forming tumours
Chondro-sarcoma
Juxta-cortical chondro-sarcoma
Mesenchymal chondro-sarcoma
Giant-cell tumours
Malignant giant-cell tumour
Bone-marrow tumours
Ewing's sarcoma
Reticulum-cell sarcoma
Lympho-sarcoma
Myeloma
Vascular tumours
Angio-sarcoma
Other connective-tissue tumours
Fibro-sarcoma
Lipo-sarcoma
Malignant mesenchymoma
Undifferentiated sarcoma
Other tumours
Chordoma
Adamantinoma of long bones
Neuro-sarcoma

In Finland, it is planned to add the following categories in the clinical classification of tumours secondary chondrosarcoma, the sub-groups of myeloma — solitary myeloma and multiple myeloma, extra-medullary plasma-cytoma and the sub-groups IgA, IgG and IgM, also haemangio-endothelioma-sarcoma haemangio-pericytoma-sarcoma, radiation sarcoma, primary malignant fibrous histiocytoma, NUD sarcoma, fibrolipo-myxoma malignum, chondro-myxoma malignum and fibro-myxoma malignum (Sorvari, 1976)

2 3 ETIOLOGY

It has been shown that genetic factors are involved in primary malignant tumours occurring in Ollier's disease and in hereditary multiple chondromatosis (Mainzer et al 1971, Lichtenstein 1972) Among patients suffering from the last-mentioned disease, chondro-sarcoma occurs in 25 % (Solomon 1974) (Marcove 1977)

In osteo-genesis imperfecta, spontaneous fractures are common and it might be supposed that there would be a high frequency of sarcoma, resulting from abundant callus formation This, however, is not the case and sarcoma of the bone is in fact rare, though individual cases have been reported (Koskinen 1958, Klenerman et al 1967)

Malignant giant-cell tumours are preceded by benign giant-cell tumours (Sabanas et al 1956, Copeland et al 1967)

In Gardner's syndrome, where the patient has carcinoma of the colon and sarcoma of the bone, the malignancy develops in a polyp in the colon, and in the bone by way of a fibrous dysplasia (Johnson et al 1972)

In Paget's disease the probability that malignancy will develop is 0 7 % — 3 0 % per year (Esposito et al 1960, MacKenzie et al 1961, Dahlin et al 1967, Folsch 1968, Price et al 1969)

The development of malignancy in fibrous dysplasia was described by Coley and Stewart in 1945 Their study revealed that those patients in whom malignant fibrous dysplasia developed had undergone radiation treatment for the bone lesion in question Radiation treatment has also often been given for Paget's disease (Tanner et al 1961, Dahlin et al 1967)

Chronic osteitis has been considered an etiological factor in the development of malignant bone tumours Streptococcus cavitae found in a fistula has been considered an irritant that causes malignancy (Lacassagne et al 1928) The incidence of malignancy in fistulating osteitis is 0 23 % per year (Poprikov 1968)

It has been shown that radiation, particularly in connection with tubercular inflammation, causes malignant bone tumours (Marie et al 1910, Cahan et al 1948) It has been found that patients who have had radiation treatment and people exposed to radiation in industrial work are more liable than others to get malignant bone tumours (Cade 1955, Mindell et al 1977) In females treated for breast cancer with a dose of 4,000 rad, there is a probability of 0 07 % — 0 22 % that malignant bone tumours will develop (Schwartz 1968, Hatfield 1970)

It has been found in experiments with animals that osteo-sarcoma can just as well be caused by a single dose of radiation as by repeated doses (Sabanas et al 1956 Steiner 1965, Arlen et al 1971, Yamanato 1971, Mindell et al 1977 Ott et al 1977) The latency time is long and it is typical that during this time the organ

in question is symptom-free The younger the patient and the larger the dose the greater is the risk of radiation sarcoma (Mindell et al. 1977) Radiation sarcoma is often caused by radiation treatment given for a benign bone lesion (Arlen et al 1971) Radiation affecting the whole body has seldom been shown to cause bone tumours, the radiation dose necessary to induce sarcoma must be large and in the cases studied the doses were usually fatal (Yamamoto 1971)

It has not been possible to demonstrate to what extent trauma may be an etiological factor in the development of primary malignant bone tumours, although some investigators are of the opinion that trauma may partly explain the greater frequency in males of such tumours (Ewing 1935 Phemister 1948, Cade 1955, Krebs et al 1963 Hellner 1966, Voutilainen et al 1967, Fisher 1971) It has been observed that sarcoma in the metaphysis sometimes penetrates all tissues but stops short at the epiphyseal line a suggested explanation is that the greater amount of growth hormone in the epiphyseal part prevents the development of osteo-sarcoma (Krebs 1962)

2 4 AGE DISTRIBUTION

There are two periods in the course of life when the risk of primary malignant bone tumour is great Ewing s sarcoma tends to occur especially between the ages of 11 and 13 and osteo-sarcoma between 16 and 18 (Price et al 1975) Chondro-sarcoma and myeloma occur most frequently between the ages of 55 and 60 (Coley et al 1938, Prevo 1950, Hoppe et al 1952, Cade 1955 Compere 1964, Lodwick 1964, Ranke 1968, Dahlin 1972) Children account for approximately 20 % of all patients suffering from primary malignant bone tumours (Dedo 1971, Grover et al. 1972, Welte et al 1974) Children and young adults are more likely than people of middle age or old people to suffer from primary malignant bone tumours (Coley et al 1938) Welte (1974) described a series of 109 children suffering from malignant tumours, and of these 13 % had primary bone tumours

2 5 RACE

Except for Ewing's sarcoma, which occurs more among white people (see Bethge, 1953), race does not appear to be a factor in the incidence of bone tumours

2 6 SEX

Primary malignant bone tumours are on the whole found more frequently in males than in females (Christensen 1925, Phemister 1948, Glenchur et al 1959, Price 1962, Foster et al 1964, Phillips 1965, Dahlin et al 1967)

2 7 LOCATION

Location is presented in Table 3

Bone sarcomas are most often located in the metaphysis of long bones Chondro-sarcoma is often also found in the pelvis and ribs Malignant giant-cell tumours are most frequently situated in the region of the knee, in the humerus and in the distal metaphysis and epiphysis of the radius, tibia and fibula (Dahlin 1972) Parosteal osteo-sarcoma and parosteal chondro-sarcoma are located juxta-cortically Individ-

Table 3 Location of primary malignant bone tumours (Coley et al 1950, Wang et al 1953, Bethge 1953, Sherman et al 1956, Coventry et al 1957, Henderson et al 1963, Dahlin 1972, Spanier et al 1975)

ual cases of osteo-sarcoma in the soft tissues have been reported (Fine et al 1956, Dahlin 1972)

Myelomas are typical in the diaphysis of the long bones, in the spine, the skull, *the pelvis and the ribs* (Dahlin 1972) 75 % of extra-medullary plasma-cytomas are situated in the region of the upper respiratory passages (Wiltshaw 1976), most frequently in the hypo-pharynx, the nose, the clavicular recess or neck glands and occasionally in the orbit, thyroid gland or abdominal cavity (Rodman et al 1968, Oberkircher et al 1972, Sasse et al 1973)

Chordomas are always located in the region of the spine, generally in the fora-

men magnum or in the sacrum (Dahlin 1972) Adamantinomas of long bones are always found in the diaphysis

90 % of all primary malignant bone tumours in the thorax are situated in the ribs (Teilbaum 1972)

2 8 SYMPTOMS AND DIAGNOSIS

2 8 1 Pain

Local pain is often the first symptom of a primary malignant bone tumour (Coley et al 1938 Aakhus et al 1963 Dahlin 1972) Severe pain felt especially in a joint means that the tumour is continuously growing (Dahlin 1972) The tumour is situated where the pain is felt except when the tumour causes radicular pains (Copeland 1967) Different tumours cause different kinds of pain It is typical of malignant giant-cell tumours that they cause slight intermittent pain (Murphy et al 1956) If a benign giant-cell tumour begins to cause pain this is always a pathognomonic symptom (Dahlin 1972) 80 % of myeloma patients have pains in the bone (Glenchur et al 1959) These pains are often radicular and accompanied by par estesias

2 8 2 Resistance to palpation

Resistance to palpation combined with a flushing and reddening of the skin are typical features of an advanced tumour (Dahlin 1972) If the tumour is not attached to the cortex of the bone tenderness is the only observable feature (Dahlin 1972) It is typical of parosteal tumours that they are palpable are attached to the surrounding tissue and feel diffuse (Dwinnel et al 1954) It has been ascertained that in 80 % of patients suffering from malignant giant-cell tumours there is a hard crepitating resistance to palpation (Williams et al 1964) In myeloma patients it has been found that 20 % showed resistance to palpation in the ribs, clavicle or skull (Glenchur et al 1959)

It is usually possible to confirm chordoma of the sacrum and also tumours of the pelvis by palpation per rectum An extra-medullary plasma-cytoma can be felt in situ (Dahlin 1972)

2 8 3 Decreased activity

Limitation of movement and a tendency to become easily fatigued are signs of a rapidly advancing tumour (Dahlin 1972) In chordoma of the sacrum, common symptoms, connected with the paresis caused by compression of the sacral roots of the spinal cord are constipation sciatic pain and numbness of the buttocks (Dahlin 1972)

2 8 4 Pathological fracture

50 % of myeloma patients have a pathological fracture at some stage of the disease (Carson et al 1955 Glenchur et al 1959) and 10 % have paraplegia, resulting from the pathological fracture of a vertebra when they first present themselves for treatment (Lumb et al 1948, Ulrich et al 1958) Pathological fracture has been certified in 5 % of sarcoma patients (Banshali et al 1963) and in 6 % of chondrosarcoma patients (Copeland 1967) when they first presented themselves for treatment

2 8 5 Decline in general health

A typical symptom of a far advanced malignant bone tumour is a decline in

2 8 SYMPTOMS AND DIAGNOSIS

2 8 1 Pain

Local pain is often the first symptom of a primary malignant bone tumour (Coley et al 1938, Aakhus et al 1963, Dahlin 1972) Severe pain, felt especially in a joint means that the tumour is continuously growing (Dahlin 1972) The tumour is situated where the pain is felt, except when the tumour causes radicular pains (Copeland 1967) Different tumours cause different kinds of pain It is typical of malignant giant-cell tumours that they cause slight intermittent pain (Murphy et al 1956) If a benign giant-cell tumour begins to cause pain, this is always a pathognomonic symptom (Dahlin 1972) 80 % of myeloma patients have pains in the bone (Glenchur et al 1959) These pains are often radicular and accompanied by parestesias

2 8 2 Resistance to palpation

Resistance to palpation, combined with a flushing and reddening of the skin are typical features of an advanced tumour (Dahlin 1972) If the tumour is not attached to the cortex of the bone, tenderness is the only observable feature (Dahlin 1972) It is typical of parosteal tumours that they are palpable, are attached to the surrounding tissue and feel diffuse (Dwinnel et al 1954) It has been ascertained that in 80 % of patients suffering from malignant giant-cell tumours, there is a hard, crepitating resistance to palpation (Williams et al. 1964) In myeloma patients it has been found that 20 % showed resistance to palpation in the ribs, clavicle or skull (Glenchur et al 1959)

It is usually possible to confirm chordoma of the sacrum and also tumours of the pelvis by palpation per rectum An extra-medullary plasma-cytoma can be felt in situ (Dahlin 1972)

2 8.3. Decreased activity

Limitation of movement and a tendency to become easily fatigued are signs of a rapidly advancing tumour (Dahlin 1972) In chordoma of the sacrum, common symptoms, connected with the paresis caused by compression of the sacral roots of the spinal cord, are constipation, sciatic pain and numbness of the buttocks (Dahlin 1972)

2 8 4 Pathological fracture

50 % of myeloma patients have a pathological fracture at some stage of the disease (Carson et al 1955, Glenchur et al. 1959) and 10 % have paraplegia, resulting from the pathological fracture of a vertebra, when they first present themselves for treatment (Lumb et al 1948, Ulrich et al 1958) Pathological fracture has been certified in 5 % of sarcoma patients (Banshah et al 1963) and in 6 % of chondrosarcoma patients (Copeland 1967) when they first presented themselves for treatment

2 8.5 Decline in general health

A typical symptom of a far advanced malignant bone tumour is a decline in

general health 50 % of myeloma patients have symptoms of this kind when they come for treatment (Glenchur et al. 1959)

2.8.6. Trauma

In earlier literature a trauma reported by the patient has been considered an etiological factor contributing to the development of a primary malignant bone tumour (Krebs et al 1963) It has not, however, been possible to define either the mechanism of injury or the severity of the trauma with sufficient exactitude to decide whether or not it was really an etiological factor 75 % of bone sarcoma patients report trauma and symptoms resulting from it (Derian et al 1968) Present-day investigators consider trauma to be an unlikely etiological factor (Hellner 1966, Copeland 1967, van der Heul et al 1967, Fisher 1971) An attempt has been made by means of tissue cultures to determine the part played by trauma, but this was not successful (Krebs et al 1963) Trauma may cause secondary spreading of the disease by releasing malignant cells into the blood stream and lymphatic ducts, and also haematoma by means of resorption Tissue pressure increases the development of metastases and extravasion (Krebs et al 1963) A developing tumour may cause symptoms similar to those in trauma (Phemister 1948)

2.8.7. Lack of symptoms

About one per cent of patients suffering from primary malignant bone tumours are symptom-free at the moment of diagnosis Extramedullary plasma-cytoma is sometimes discovered by chance when the nose and throat are being examined (Dahlin 1972)

2.8.8. Duration of symptoms

The symptoms of primary malignant bone tumours usually last about 1—3 months before they are diagnosed Exceptions are chondro-sarcoma, for which symptoms may last 11—12 months before diagnosis and parosteal osteo-sarcoma, the symptoms of which may go on for years (O'Neal et al. 1952)

2.9 X-RAY EXAMINATIONS

2.9.1. Plain radiography

Radiological diagnosis of primary malignant bone tumours is difficult (Gold 1975) The most important method of examination is plain radiography, by means of which 90 % of bone tumours can be revealed (Lodwick 1964, Ranke 1968)

In diagnosing bone tumours by X-ray the following factors are taken into account the radiological location of the tumour, its structure and its relationship to the surrounding tissue (Ranke 1968, Dedo 1971)

With the help of a computer it is usually possible by analysing the X-rays to make a histo-pathological diagnosis of the bone tumour before starting treatment (Lodwick 1964, Lodwick et al 1965, 1970, Virtama et al 1979) It is possible in this way to provide the patient with the best possible treatment

2.9.2. Angiography

Angiography is an important X-ray technique for diagnosing bone tumours it gives a good idea of the size and location of the tumour its relationship to the surrounding tissue its haemodynamics and its rapidity of growth (Kittredge et al

1970, Honcomp et al 1973, Gold 1975, Jacobs 1976) Angiography is no substitute for biopsy in making a histo-pathological diagnosis (Gold 1975) but is often a great help in deciding where to take the biopsy sample from (Jacobs 1976) The significance of angiography does not lie in its diagnostic value, but rather in the planning of treatment (Virtama 1979) About 25 % of angiographies have diagnostic value (Voegeli et al 1976) Angiography provides valuable additional information about the degree of malignancy of the tumour the development of secondary malignancy, the probability of recurrence, possibility of treatment and checking the progress of the disease (Koskinen et al 1968 Yagmai et al 1971 Honkomp et al 1973)

2 9 3 Lymphography

Lymphography is a method that has not been much used for determining the degree of spreading of primary malignant bone tumours In a dissertation published in 1976 Tallroth found that the spreading of a tumour into the lymphatic ducts could be determined by means of lymphography in 100 % of reticulum cell sarcomas in 57 % of osteo sarcomas and in 50 % of Ewing s sarcomas In cases where the tumour has spread into the lymphatic ducts it is especially important to think carefully before embarking on any far-reaching treatment of the primary tumour (Herzog 1972 Rao et al 1977) Bone tumour metastases in the lymphatic ducts are more common than was earlier thought (Macintosh et al 1975)

2 9 4 Other examinations

The advantage of scintigraphy over many other radiological methods for studying bone tumours is that it is less exhausting for the patient It is also cheap Nowadays pyrophosphates, polyphosphates and diphosphonates labelled Tecnetium 99 m are much used in bone scintigraphy The scan is compatible with X-ray findings in 75 % of cases (Holsti et al 1967, Tong et al 1968, Nordman et al 1977) Scintigraphy does sometimes give incorrect positive findings, but generally the strong tracer uptake correlates with the high degree of bone destruction (Aho et al 1973) The following are some of the advantages of scintigraphy (McCormack 1975 Nordman et al 1977)

- it is indicated in all examinations for the degree of spreading of bone tumours
- identification of primary focus is earlier than with other X-ray examinations
- it makes possible determination of polyostotic changes
- it makes possible determination of early and late as well as skip metastases in the medulla
- it provides the possibility of following the effects of treatment
- it provides the possibility of using radiopharmaceutical drugs, especially for myeloma
- it determines what other X-ray examinations are necessary

In cases where the tumour is known to be polyostotic, scintigraphy of the whole body is indicated For example, 30 % of chordomas and Ewing s sarcomas are polyostotic (McCormack 1975)

Tomography is significant for the differential diagnosis of inflammation and can reveal possible sequesters Computer tomography gives a good idea of the spread of the tumour into the bone mar-

row and the metastases therein (de Santos et al 1978, Virtama 1979)

Some investigators have made use of thermography for studying primary bone tumours, but its precise significance is not yet clear (Farrell et al 1971)

2 10 LABORATORY STUDIES

2 10 1 General

Laboratory studies are important in the diagnosis of primary malignant bone tumours and also for determining the degree of spreading of the tumour In sarcoma patients with a far advanced tumour there is usually an elevated erythrocyte sedimentation rate, reduced Hb and pathological alkaline phosphatase It is possible by studying the large enzymes to distinguish between alkaline phosphatase originating in the bones and that which stems from the liver The elevated level of alkaline phosphatase originating in the bones which occurs in sarcomas arising from Paget s disease returns to normal when the tumour is removed (McKenna et al 1964) It is also possible by means of laboratory tests to follow the results of treatment (O Hara et al 1968 Folsch 1968 Derian et al 1972)

2 10 2 Laboratory diagnosis of myeloma

The earliest laboratory findings concerning myeloma were made in the last century Bence-Jones discovered in 1845 that myeloma patients had albumin in their urine and he later isolated what is known as Bence Jones proteinuria If electrophoresis and a precipitation reaction are used it is possible to confirm Bence-Jones proteinuria in 85 % of myeloma patients (Carson et al 1955, Martinez-Maldonado et al 1971) At the moment of diagnosis 60 % of myeloma patients have an erythrocyte sedimentation rate of more than 50 mm/t and Hb less than 120 g/l (Carson et al 1955, Leawell et al 1966) Leukopenia occurs in 60 % and leukocytosis in 20 % of myeloma patients (Lumb 1948) More than half of these patients suffer from pathological lympho-cytosis One third of myeloma patients have a pathological number of plasma cells in the peripheral blood (Glenchur et al 1959 Drivsholm 1965)

In 80 % of myeloma patients plasma albumin is as high as 80 g/l and more (Lumb et al 1948 Drivsholm 1965) 20 % —40 % of myeloma patients have hypercalcemia (Carson et al 1955) Alkaline phosphatase is elevated in 30 % of myeloma patients (Esposito et al 1960) whereas in Paget s disease it is elevated in over 95 % of patients (Leawell et al 1966 Drivsholm 1965)

Electrophoresis and immuno-electrophoresis are important methods for studying serum immunoglobulins By electrophoretic means it is possible to make pathological and diagnostic findings in the serum of 90 % of myeloma patients (Drivsholm 1965 Leawell et al 1966) Immunoglobulins are usually of the IgG type IgA cases are less than half as numerous as IgG The IgM type accounts for less than one per cent of cases (Leawell et al 1966) Only three cases of the IgE type have been reported in literature (Wasastjarna 1974) Biclonal myeloma containing two M-components is rare (Wasastjarna 1974)

Bence-Jones proteinuria is found in the urine of 18 % of myeloma patients with normal electrophoresis In studying the electrophoresis of serum and urine a diagnostic result is achieved in 93 % of cases

(Leawell et al 1966) A similar finding has been made by Azar (1972) among others

Ten per cent of myeloma patients suffer from amyloidosis when they come for treatment (Carson et al 1955) The cause of amyloidosis is the sensitivity of tissue to paraproteins (Carson et al 1955, Martinez-Maldonado et al 1971) In myeloma patients it is amyloidosis that is the principal cause of renal insufficiency Renal function is impaired in 40 % of myeloma patients (Drivsholm 1965)

Bone marrow tests give positive diagnostic results in 80 % of myeloma cases (Drivsholm 1965, Leawell et al 1966)

2 11 HISTO-PATHOLOGICAL EXAMINATIONS

Because of the quality of the tissue to be studied, histo-pathological examination of bones may be difficult Moreover, bone tumours are rare and the result is that very few pathologists are experts in the histo-pathology of bones It is nevertheless necessary to have histo-pathological confirmation before bone tumours can be treated clinically If a benign bone lesion is diagnosed as a malignant tumour the treatment given may involve irreversible loss and on the other hand, to diagnose a malignant tumour as benign will be fatal for the patient (Copeland 1967)

In order to be reliable, pre-operative biopsy must be performed as open biopsy (Hajdu et al 1971) Some investigators think there is a risk that open biopsy may cause metastases to develop

Some people favour the use of needle biopsy (Schajowicz et al 1968, Hajdu et al 1971, 1975) For giant-cell tumours it is an untrustworthy method (Williams et al 1964) Biopsy means a less favourable prognosis (Lindbom et al. 1961) and needle biopsy does not generally lead to a clear diagnosis (Aakhus et al 1963) Study of frozen sections is difficult for the pathologist Some investigators consider that the accuracy of such a study is not greater than 30 %—75 % (Derian et al 1968) Copeland (1967) expressed the following thought about the study of frozen sections and this we may consider realistic· » .it is valuable for an experienced pathologist, but measures like amputation should never be undertaken without first doing a paraffin examination »

2 12 DIAGNOSIS

2 12 1. General

The possibility of primary malignant bone tumour is not always taken into account and this is one reason why diagnosis is sometimes difficult (Dissing et al 1977, Salenius 1976) The patient is treated on the basis of an incorrect diagnosis, for example dislocation of a joint, bruising, anaemia, kidney disease, or fever (Dissing et al 1977) Diagnosis of bone tumours must be based on the results of clinical tests — radiography, laboratory and histopathological study — and a synthesis of the findings (Cade 1955, Compere 1964, Hellner 1966, Copeland 1967, Koskinen 1976, Sissons 1977, Compere 1978)

2.12 2. Differential diagnosis

In osteogenesis imperfecta, hyperplastic callus simulates osteo-sarcoma (Baker 1967) In connection with trauma, myositis ossificans resembles a bone tumour and is sometimes difficult to distinguish from osteo-sarcoma Furthermore, if there is a

slight trauma, the bruises may make diagnosis more difficult (Banshali et al 1963) Stress fracture and low-grade osteo-myelitis in which there is slight periostitis resembles inflammatory osteo-sarcoma (Hellner 1966, Orava et al 1978) In differential diagnosis, the progress of the disease and the failure of anti-biotics to take effect are important factors (Hellner 1966) Bouts of slight fever, elevated erythrocyte sedimentation rate, leucocytosis and serological findings are not conclusive (Hladik et al 1967) Even in biopsy, it is difficult to distinguish between Ewing's sarcoma and osteo-myelitis (Banshali et al 1963, Hellner 1966) Benign bone lesions are frequently misdiagnosed as malignant, especially in children A misdiagnosis, either in children or adults, may have tragic consequences (Copeland 1964)

2 13 TREATMENT

2 13 1 General

There are many different ideas about how to treat primary malignant bone tumours (Ranke 1962) Because treatment of bone tumours often severely disables the patient or leads to death, the great problem is how to plan the treatment (Compere 1964) It is the histological diagnosis of bone tumours that finally decides the treatment to be given (Reichmann 1976 Aho 1979) Recent improvements have made it possible to make a correct histological diagnosis pre-operatively and this has made it easier to choose the correct treatment

2 13 2 Radical ablative surgery

Until recently the treatment for primary malignant bone tumour has been radical ablative surgery (Copeland 1967, Dahlin 1972) The general belief has been that other forms of treatment are ineffective (Coventry et al 1957, Nilsonne 1965, Copeland 1967, Wagner et al 1967) According to Compere (1964)) only 10 % of patients treated with ablative surgery have been cured The traumatic effect of ablative surgery can only be minimized by maximizing medical, surgical, pathological and psychological knowledge (Enelow 1975) In individual cases a permanent cure has been effected by super-radical ablative surgery — hemipelvectomy and hemicorporectomy (Higinsbotham et al 1956, Pack 1956, Koskinen 1967, Franklin et al 1977, Miller 1977, Sneppen et al 1978), but there is no difference in the five-year survival rates (Foster et al 1964) Although radical ablative surgery is by no means always curative it has been reported that it definitely slows down the development of metastases and thus prolongs the patient's life (Nilsonne 1965) If the tumour recurs in the stump of an amputated limb this means that the surgery was not radical (Dahlin et al 1967)

2 13 3 Radical resection

In the treatment of malignant bone tumours the method of radical resection has developed considerably in recent years The resected bone is replaced by an autogenic bone an allograft or a prosthesis A vascular bone transplant is possible in special cases (Weiland et al 1978) A precondition for the success of radical resection is that the tumour can be removed in its entirety The method is best suited for parosteal osteo-sarcoma of the long bones chondro-sarcoma giant-cell tumours and in special cases fibro-sarcoma (Volkov 1970 Parrish 1972 Ottolenghi 1973 Wil-

son 1975, Burrows et al 1975, Meyers 1977, Smith et al 1977, Koskinen 1978, Koskinen et al 1979)

2 13 4 Local resection

In local resection, the distance between the tumour and the resection line is less than five centimetres The smaller the distance, the greater is the possibility that tumour cells will remain behind Local resection has proved to be a successful method especially in treating chondrosarcoma in small bones and also giant-cell tumours Local resection has also been used rather often in the past in the treatment of sarcoma of long bones Early results for patients treated in this way were often good but recurrence of the tumour or metastases developed rapidly In the series reported by Lindbom (1961) recurrence of tumour or development of metastases was very rapid

2 13.5 Local evacuation

Neither local evacuation, abrasion nor electro coagulation are acceptable methods of treatment for any kind of malignant bone tumour When giant-cell tumours have been treated in this way it has led to the »paradoxical response» described by Herenden (see Murphy et al 1956) in which the malignancy of the tumour is increased

2 13 6 Palliative surgery

Palliative surgery, in which some tumour tissue is knowingly left in place, is sometimes necessary in treating a bone tumour patient in order to dispel severe pain or relieve the necrotization of the tumour (Cade 1955)

Palliative surgical treatment of metastases has in individual cases led to good results, even with a ten-year follow-up and longer (Francis et al 1962, Dahlin et al. 1967, Tala et al 1967, Sellors 1970, Scanlon 1972, Holmes et al 1977) In the treatment of all malignancies it has been found that the patient's own resistance is longer if the greater part of the tumour is removed or destroyed (Reichmann 1976)

2 13 7. Radiation treatment

Primary malignant bone tumours can be classified as sensitive to radiation, moderately sensitive to radiation and resistant to radiation (Table 4) Radiation treatment has a clear effect on tumours that are sensitive to it and the significance of radiation treatment has increased in recent years (Cade 1955, Aakhus et al 1963, Heilmann 1971, Holsti et al 1977)

Radiation treatment is of very little use in the treatment of bone and cartilage-forming tumours, neither is it of much value for malignant giant-cell tumours Bone marrow tumours react well to radiation treatment Radiation treatment is an important part of therapy for Ewing's sarcoma and is the main form of treatment for reticulum-cell sarcoma and lympho-sarcoma Reticulum-cell sarcoma and lympho-sarcoma are curable by radiation and mutilating ablative surgery is contra-indicated in the treatment of these tumours (von Ronnen et al 1974, Nordman 1979)

Vascular tumours, connective-tissue tumours and other malignant bone tumours are generally somewhat sensitive to radiation (Table 4)

In recent years the significance of preoperative radiation treatment has declined considerably owing to the increase in bone

slight trauma the bruises may make diagnosis more difficult (Banshali et al 1963) Stress fracture and low-grade osteo-myelitis in which there is slight periostitis resembles inflammatory osteo-sarcoma (Hellner 1966, Orava et al 1978) In differential diagnosis, the progress of the disease and the failure of anti-biotics to take effect are important factors (Hellner 1966) Bouts of slight fever, elevated erythrocyte sedimentation rate, leucocytosis and serological findings are not conclusive (Hladik et al 1967) Even in biopsy, it is difficult to distinguish between Ewing s sarcoma and osteo-myelitis (Banshali et al 1963 Hellner 1966) Benign bone lesions are frequently misdiagnosed as malignant, especially in children A misdiagnosis, either in children or adults may have tragic consequences (Copeland 1964)

2 13 TREATMENT

2 13 1 General

There are many different ideas about how to treat primary malignant bone tumours (Ranke 1962) Because treatment of bone tumours often severely disables the patient or leads to death the great problem is how to plan the treatment (Compere 1964) It is the histological diagnosis of bone tumours that finally decides the treatment to be given (Reichmann 1976 Aho 1979) Recent improvements have made it possible to make a correct histological diagnosis pre-operatively and this has made it easier to choose the correct treatment

2 13 2 Radical ablative surgery

Until recently the treatment for primary malignant bone tumour has been radical ablative surgery (Copeland 1967, Dahlin 1972) The general belief has been that other forms of treatment are ineffective (Coventry et al 1957, Nilsonne 1965, Copeland 1967, Wagner et al 1967) According to Compere (1964)) only 10 % of patients treated with ablative surgery have been cured The traumatic effect of ablative surgery can only be minimized by maximizing medical surgical pathological and psychological knowledge (Enelow 1975) In individual cases a permanent cure has been effected by super-radical ablative surgery — hemipelvectomy and hemicorporectomy (Higinsbotham et al 1956 Pack 1956 Koskinen 1967, Franklin et al 1977, Miller 1977 Sneppen et al 1978) but there is no difference in the five-year survival rates (Foster et al 1964) Although radical ablative surgery is by no means always curative it has been reported that it definitely slows down the development of metastases and thus prolongs the patient s life (Nilsonne 1965) If the tumour recurs in the stump of an amputated limb this means that the surgery was not radical (Dahlin et al 1967)

2 13 3 Radical resection

In the treatment of malignant bone tumours the method of radical resection has developed considerably in recent years The resected bone is replaced by an autogenic bone an allograft or a prosthesis A vascular bone transplant is possible in special cases (Weiland et al 1978) A precondition for the success of radical resection is that the tumour can be removed in its entirety The method is best suited for parosteal osteo sarcoma of the long bones chondro-sarcoma giant-cell tumours and in special cases fibro-sarcoma (Volkov 1970 Parrish 1972 Ottolenghi 1973 Wil-

The relationship between the curative possibilities of radiation treatment and the size of the tumour is clear If the area of the malignancy is small, it responds better to radiation and it is thus important to remove the tumour as far as possible by means of palliative surgery, before giving radiation treatment Sub-clinical micro-metastases can be destroyed with a dose of 5,000—6 000 rad, but a primary tumour cannot be cured with such a dose Radiation treatment is thus indicated for metastases in the lungs or regional lymph nodes Two successive doses of 200 rad are indicated for preoperative radiation before biopsy (von Ronnen et al 1974)

Palliative radiation treatment is important for slowing down temporarily the growth of a tumour in cases where surgical measures are impossible on account of the anatomical location or because of vital function Such tumours are often situated in the base of the skull, the spine or the pelvis (Beck et al 1976)

Solitary myeloma and extra-medullary plasma-cytoma can be cured by radiation

The clinically effective radiation dose for osteo-sarcoma is between 4 000 and 9 000 rad given 1 000 rad per week (Woodard et al 1947)

According to present ideas radiation treatment alone, without up-to-date cytostat treatment is not indicated (Beck et al 1976)

2 13 8. Treatment with cytostatic agents

Treatment with cytostatic agents has developed considerably in recent years Earlier it was mostly used palliatively and as an adjunct to radiation treatment Nowadays cytostat treatment is used actively and as an integral part of overall treatment (Sack 1976) There have been big changes in the doses of drugs given The intra-arterial administration of cytostatic agents is at the experimental stage (Oka 1970) Different drug combinations and mammoth doses have given encouraging results (Lochshin et al 1963, Price et al 1975, Rosen 1975, Akahoshi et al 1977, Copeland 1977, Huvos et al 1977, Jaffe 1977, Kotz et al 1977, Gröhn et al 1978, Nikkanen 1978) Cytostat treatment carries with it the risk of a carcinogenic effect Renner (1971) found that a primary benign tumour became malignant owing to the effect of cytostat treatment The sensiti-

resections Radiation treatment de-vitalizes the surrounding tissue and reduces the likelihood of success of bone transplant (Koskinen et al 1968, McCormack 1978) The schema for treatment proposed by Ferguson (1940), in which preoperative necrotizing radiation and late amputation are used, *still has its supporters* (Cederlof et al *1961*, *Aakhus et al* 1963, *Lissner* 1969, Heilman 1971) There is still today uncertainty about the value of preoperative radiation treatment *Preoperative radiation* in osteo-sarcoma is without value (von Ronnen et al 1974, *Nordman 1979*)

different types of tumour As far as prognosis is concerned no difference between the sexes has been discovered (Dahlin et al 1969) Prognosis has improved as treatment has developed (Lochshin et al 1963, Dahlin et al 1969)

2.14 2 Bone-forming tumours

2 14 2 1 Osteo-sarcoma

The 5-year survival rate for osteo-sarcoma varies between 10 % and 30 % in different studies The results of surgery are better than those of radiation.

There is no certain evidence that preoperative radiation treatment improves the prognosis for sarcoma (Beck et al 1976)

The location of the tumour is important for prognosis (Holsti et al. 1973) The prognosis for tumours in the elbow and knee joints is better if they are located distally than if they are proximally situated (Coventry et al 1957, Dahlin et al 1967) There is a good prognosis for tumours of the

	279	19.0	58	3.4	147	17.0

vity of primary malignant bone tumours to cytostat treatment is different from their sensitivity to radiation

Cytostatic agents have long been the basic treatment for myeloma With cytostats it has often been found that metastases either disappear or become smaller (Sack 1976) There is no information available as yet about the effect on prognosis in a long-term follow-up Before the introduction of massive cytostat treatment, 80 % of osteo-sarcoma and Ewing's sarcoma patients died within two years after the making of the diagnosis With the present treatment 80 % are still alive after two years (Ivins et al 1976, Jenkin et al 1976, Dissing et al 1977, Jaffe 1977)

In treating recurrence of tumour and metastases the most important method is combined surgical and cytostat treatment (Oldhoff 1970)

2 13 9. Immunological treatment

The immunological treatment of primary malignant bone tumours is at the experimental stage Encouraging results have been achieved in individual cases (Koskinen 1976, Tallberg 1976, Salenius 1977) In connection with immunological resistance, the spontaneous disappearance of tumours has been observed (Copeland 1975)

2 13.10 Interferon

For the treatment of osteo-sarcoma and multiple myeloma, interferon is at the experimental stage and preliminary results are encouraging (Cantell 1978 Idenstrom et al, Mellstedt et al 1979)

2.13.11. Treatment of pathological fractures

Pathological fractures are common among bone tumour patients Surgical treatment of fractures is very important for relieving pain One useful method is intra-medullary nailing of long bones, combined with radiation treatment (Marcove et al 1967, Phelan 1968, Cech 1970, Koskinen et al 1973) Prophylactic osteosynthesis is necessary, for example, if there is a large myeloma nodule in the diaphysis of the femur There is no evidence that nailing leads to the spread of a tumour (Phelan 1968, Harrington 1977)

Marcove's report (1967) on patients who underwent surgery after pathological fracture showed that 40 % lived for over six months postoperatively and 34 % for over a year If the patients had multiple fractures, 39 % lived 1—6 months and 26 % more than one year Complications after surgery were common

2.13.12. General treatment

Care of patients suffering from primary malignant bone tumours is very important in order to improve their general condition and their immunity Many patients are seriously disabled by the disease and its treatment, their resistance and mental stability being shaken The patient must be treated as a totality

2 14 PROGNOSIS

2 14 1 General

The prognosis for primary malignant bone tumours is considered to be serious (Platt 1962), though it is very different for

Table 6 Five-year and ten-year survival rates for osteo-sarcoma *in different reports*

Mandibula (Garrington et al 1967)	22	41 0	13	38 0

lower jaw (Kragh et al 1958, Garrington et al 1967, Finkelstein 1967)

The prognosis for osteogenic sarcoma in soft tissue is the same as for tumours originating in bone (Fine et al 1956)

The prognosis for osteo-sarcoma is better for females than for males (Lindbom et al 1961, Platt 1962) This may be because of the location of tumours Tumours in females are more often situated in the limbs (Foster et al 1964)

It is generally thought that the age at which tumours develop has no effect on prognosis (Dahlin 1967) In many studies, however, the prognosis has been better for patients between 20 and 40 years old (Coley et al 1940, Cederlof et al 1961, Price 1966) The prognosis for osteo-sarcoma is better when symptoms are of long duration than when there is a tumour that has produced symptoms only for a short time (Cederlof et al 1961)

Prognosis is poor for osteo-sarcoma that results from Paget's disease (Lockshin et al 1963, Ross 1964, McKenna et al 1964, Price et al 1969) For osteo-sarcomas that developed from Paget's disease Platt (1962) reported a 5-year survival rate of 2 % and Price (1969) a 5-year survival rate of 5 %

On the other hand, the prognosis for tumours of the lower jaw is rather good (Finkelstein 1967)

The prognosis for osteo-sarcoma is better if the tumour can be removed radically by surgical means as soon as the diagnosis is certain In osteo-sarcoma conservative ablative treatment is often sufficient (Sneppen et al 1978) Osteo-sarcoma also produces metastases very rapidly in the lungs, liver and bones, it also recurs locally Ten per cent of osteo-sarcoma patients have metastases in the regional lymph nodes when they come for treatment (Caceres et al 1969) If the patient has metastases in the regional lymph nodes the prognosis is worse than otherwise (Baumann 1970 Rao et al 1977) In cases of osteo-sarcoma it has been found that radiation treatment either makes them disappear, or at least reduces them in size (Francis et al 1962) Removal of the regional lymph nodes worsens the prognosis in cases of osteo-sarcoma (Rao et al 1977) In osteo-sarcoma patients who survived for more than ten years there was no clear explanation as to why these had survived and not the others (O Hara et al 1968)

2 14 2 2 *Parosteal osteo-sarcoma*

It is typical of parosteal osteo-sarcoma that the prognosis is better than for osteo-sarcoma in general and also that late metastases may develop as long as sixteen years after primary treatment (Shaglietti et al 1962, van der Heul et al 1967, Wolfel et al 1969) After local excision the tumour always recurs (Dwinnel et al 1954, Stevens et al 1957)

The recommended treatment for parosteal osteo-sarcoma is resection combined with bone transplant, or amputation (Shaglietti et al 1962, van der Heul et al 1967) A small tumour which has histopathologically low-grade malignancy is treated by »en bloc» resection, large tumours by amputation, Pre-operative radiation is not recommended (Wolfel et al 1969) The plan for treatment must be made on the basis of clinical examination and X-ray examination (Wolfel et al 1969)

The five-year survival rate for parosteal osteo-sarcoma is more than 50 % (Copeland 1967) If adequate treatment is given early enough the majority of patients recover (Dahlin 1972) The five-year survival rate for parosteal osteo-sarcoma does not correspond exactly to the progress of the disease, because late metastases are common There are no figures available for long-term follow-ups of ten years or more For individual cases of osteo-sarcoma, the prognosis is better than for other primary malignant bone tumours

Recurrence of the tumour is common in parosteal osteo-sarcoma (van der Heul et al 1967) and the tumour forms metastases in the same organs as osteo-sarcoma in general

2 14.3. Cartilage-forming tumours

2 14.3 1 *Chondro-sarcoma*

The best treatment for all chondro-sarcomas is radical surgery (Lindbom et

Table 9 Principles for treating parosteal osteo-sarcoma (van der Heul et al 1967)

— [illegible]
— [illegible]
— [illegible]
— [illegible]
— excision of new tumour does not prevent further recurrence, on the contrary a further tumour will develop even more rapidly

Table 10 Five-year survival rate for parosteal osteo-sarcoma when treated surgically

Investigator(s)	Patients No	5-year survival No	%
Dwinnel et al (1954)	15	10	66 7

Dahlin (1972)	25	19	76 0
	74	51	68 9

al 1961, Foster et al 1964) Chondro-sarcoma is localized in 50 % of patients when they present themselves for treatment (Foster et al 1964) A biopsy should be carried out before any treatment is given (Dahlin 1972) The results of local excision in chondro-sarcoma seem to be good, but this procedure fails to prevent metastases from forming (Lindbom et al 1961, Dahlin 1972) If chondro-sarcoma is treated radically, either the tumour recurs or metastases follow quickly and the prognosis is poor (Copeland 1967) Radiation treatment has no effect on chondro-sarcoma, but in tumours located in the pelvis and in the spine it has a clear palliative effect and suppresses patients' symptoms for a long time If chondro-sarcoma is treated in the same way as osteosarcoma, the results age good (Marcove 1977) As far as prognosis is concerned there is no difference between the sexes

The histo-pathological distribution of chondro-sarcoma is important for prognosis The best prognosis is that for juxta-cortical chondro-sarcoma and the worst is for menenchymal, which forms early metastases (Dahlin 1972, Wu et al 1977)

The prognosis for chondro-sarcoma is better when it is peripheral than when it is centrally situated It is seldom possible to perform radical treatment when the tumour is in the spinal or pelvic region and therefore the results of treatment are usually poor (Dahlin et al 1956)

The 5-year survival rates for chondro-sarcoma patients undergoing radical surgery are between 30 % and 70 % The results of palliative surgery are exceptionally unfavourable In Lindbom's series (1961) metastases developed in 75 % of the patients Phelan (1964), reported that metastases developed in all patients treated with local surgery There are few reports dealing with chondro-sarcoma patients who have received radiation treatment only and such reports as there are show extremely poor results Spontaneous recovery has occasionally been reported (McLaughlin et al 1979)

Table 11 Five-year survival rate for chondro-sarcoma according to method of treatment

Investigator(s) and treatment	Patients No	5-year survival No	%

Copeland (1967) radical resection or radical amputation	118	45	38 1
	467	215	46 0

2 14 4 Giant-cell tumours

2 14 4 1 *Malignant giant-cell tumour*

The treatment for giant-cell tumours is the same as for osteo sarcoma (Jaffe 1953, Hutter et al 1962) The present treatment, radical resection and bone transplant (autotransplant or allotransplant) has given encouraging results in individual cases (Jaffe 1955, Koskinen 1978) Palliative resection or evacuation leads to recurrence of the tumour in 85 % of cases (Goldenberg 1970 Koskinen 1978) Radiation treatment usually has no effect on giant-cell tumours but it has been found to give some relief in the case of tumours situated in the pelvic region (Cade 1955 Murphy et al 1956 Dahlin 1972) Herenden (1924) described the »paradoxical responce», in which radiation treatment activates giant-cell tumours in a more malignant direction

The prognosis for malignant giant-cell tumours is good if primary treatment is radical, and there is no recurrence of tumour nor do metastases develop (Koskinen et al 1978) Prognosis is usually poor if the tumour recurs (Dahlin 1972 Koskinen 1978) Radiation treatment has no effect on a recurrent tumour (Williams et al 1964)

2 14 5 Bone-marrow tumours

2 14 5 1 *Ewing's sarcoma*

Ewing s sarcoma is a tumour that is sensitive to radiation and produces early metastases (Copeland 1967) For this reason the tumour has more frequently been treated with radiation than by surgery (Banshali et al. 1963, Jenkin et al 1975) Patients suffering from Ewing s sarcoma are young and thus treatment must meet special demands No cases of spontaneous recovery have been recorded (Bethge 1953)

Results of treatment vary Some have considered the disease to be hopeless and as recently as 1964 Dahlin reported that only one per cent of Ewing's sarcoma patients recovered as a result of treatment Prognosis is considered to be slightly better for women than men, because tumours are usually nearer the periphery in women (Foster et al 1964)

The results of radiation treatment and radical surgery are similar The 5-year survival rate is approximately 10 % Results of treatment have improved somewhat in the last few years because patients have come sooner for treatment Diagnostic improvement has also had a positive effect (Foster et al 1964)

25 % of patients suffering from Ewing s sarcoma are found to have metastases when they present themselves for treatment (Banshali et al. 1963) Because of the early formation of metastases, preoperative radiation combined with amputation after 4—6 months is still practised as a method of treatment The significance of surgical treatment for Ewing's sarcoma has not lessened (Banshali et al 1963) Palliative radiation treatment is useful in cases where the tumour is far advanced (Dahlin et al 1961) 75 % of those suffering from Ewing s sarcoma have either died or are in the terminal phase of the disease within two years of its being diagnosed (Copeland 1967, Baird et al 1963)

Surgical treatment of distant metastases has in certain cases proved successful (Macintosh et al 1975) Encouraging results have been achieved in recent years when micro-metastases have been treated

al 1961, Foster et al 1964) Chondro-sarcoma is localized in 50 % of patients when they present themselves for treatment (Foster et al 1964) A biopsy should be carried out before any treatment is given (Dahlin 1972) The results of local excision in chondro-sarcoma seem to be good, but this procedure fails to prevent metastases from forming (Lindbom et al 1961, Dahlin 1972) If chondro-sarcoma is treated radically, either the tumour recurs or metastases follow quickly and the prognosis is poor (Copeland 1967) Radiation treatment has no effect on chondro-sarcoma, but in tumours located in the pelvis and in the spine it has a clear palliative effect and suppresses patients' symptoms for a long time If chondro-sarcoma is treated in the same way as osteosarcoma, the results age good (Marcove 1977) As far as prognosis is concerned there is no difference between the sexes

The histo-pathological distribution of chondro-sarcoma is important for prognosis The best prognosis is that for juxtacortical chondro-sarcoma and the worst is for menenchymal, which forms early metastases (Dahlin 1972, Wu et al 1977)

The prognosis for chondro-sarcoma is better when it is peripheral than when it is centrally situated It is seldom possible to perform radical treatment when the tumour is in the spinal or pelvic region and therefore the results of treatment are usually poor (Dahlin et al 1956)

The 5-year survival rates for chondro-sarcoma patients undergoing radical surgery are between 30 % and 70 % The results of palliative surgery are exceptionally unfavourable In Lindbom's series (1961) metastases developed in 75 % of the patients Phelan (1964), reported that metastases developed in all patients treated with local surgery There are few reports dealing with chondro-sarcoma patients who have received radiation treatment only and such reports as there are show extremely poor results Spontaneous recovery has occasionally been reported (McLaughlin et al 1979)

2 14 4 Giant-cell tumours

2 14 4 1 *Malignant giant-cell tumour*

The treatment for giant-cell tumours is the same as for osteo-sarcoma (Jaffe 1953, Hutter et al 1962) The present treatment, radical resection and bone transplant (autotransplant or allotransplant) has given encouraging results in individual cases (Jaffe 1955 Koskinen 1978) Palliative resection or evacuation leads to recurrence of the tumour in 85 % of cases (Goldenberg 1970 Koskinen 1978) Radiation treatment usually has no effect on giant-cell tumours but it has been found to give some relief in the case of tumours situated in the pelvic region (Cade 1955 Murphy et al 1956, Dahlin 1972) Herenden (1924) described the »paradoxical responce», in which radiation treatment activates giant-cell tumours in a more malignant direction

The prognosis for malignant giant-cell tumours is good if primary treatment is radical and there is no recurrence of tumour nor do metastases develop (Koskinen et al 1978) Prognosis is usually poor if the tumour recurs (Dahlin 1972, Koskinen 1978) Radiation treatment has no effect on a recurrent tumour (Williams et al 1964)

2 14 5 Bone-marrow tumours

2 14 5 1 *Ewing's sarcoma*

Ewing s sarcoma is a tumour that is sensitive to radiation and produces early metastases (Copeland 1967) For this reason the tumour has more frequently been treated with radiation than by surgery (Banshali et al 1963 Jenkin et al 1975) Patients suffering from Ewing s sarcoma are young and thus treatment must meet special demands No cases of spontaneous recovery have been recorded (Bethge 1953)

Results of treatment vary Some have considered the disease to be hopeless and as recently as 1964 Dahlin reported that only one per cent of Ewing s sarcoma patients recovered as a result of treatment Prognosis is considered to be slightly better for women than men, because tumours are usually nearer the periphery in women (Foster et al 1964)

The results of radiation treatment and radical surgery are similar The ▮ year survival rate ▪ approximately 10 % Results of treatment have improved somewhat in the last few years because patients have come sooner for treatment Diagnostic improvement has also had a positive effect (Foster et al 1964)

25 % of patients suffering from Ewing's sarcoma are found to have metastases when they present themselves for treatment (Banshali et al 1963) Because of the early formation of metastases, preoperative radiation combined with amputation after 4—6 months ▪ still practised as a method of treatment The significance of surgical treatment for Ewing s sarcoma has not lessened (Banshali et al 1963) Palliative radiation treatment is useful in cases where the tumour is far advanced (Dahlin et al 1961) 75 % of those suffering from Ewing s sarcoma have either died or are in the terminal phase of the disease within two years of its being diagnosed (Copeland 1967, Baird et al 1963)

Surgical treatment of distant metastases has in certain cases proved successful (Macintosh et al 1975) Encouraging results have been achieved in recent years when micro-metastases have been treated

al 1961, Foster et al 1964) Chondro-sarcoma is localized in 50% of patients when they present themselves for treatment (Foster et al 1964) A biopsy should be carried out before any treatment is given (Dahlin 1972) The results of local excision in chondro-sarcoma seem to be good, but this procedure fails to prevent metastases from forming (Lindbom et al 1961, Dahlin 1972) If chondro-sarcoma is treated radically, either the tumour recurs or metastases follow quickly and the prognosis is poor (Copeland 1967) Radiation treatment has no effect on chondro-sarcoma, but in tumours located in the pelvis and in the spine it has a clear palliative effect and suppresses patients' symptoms for a long time If chondro-sarcoma is treated in the same way as osteo-sarcoma, the results age good (Marcove 1977) As far as prognosis is concerned there is no difference between the sexes

The histo-pathological distribution of chondro-sarcoma is important for prognosis The best prognosis is that for juxta-cortical chondro-sarcoma and the worst is for menenchymal, which forms early metastases (Dahlin 1972, Wu et al 1977)

The prognosis for chondro-sarcoma is better when it is peripheral than when it is centrally situated It is seldom possible to perform radical treatment when the tumour is in the spinal or pelvic region and therefore the results of treatment are usually poor (Dahlin et al 1956)

The 5-year survival rates for chondro-sarcoma patients undergoing radical surgery are between 30% and 70% The results of palliative surgery are exceptionally unfavourable In Lindbom's series (1961) metastases developed in 75% of the patients Phelan (1964), reported that metastases developed in all patients treated with local surgery There are few reports dealing with chondro-sarcoma patients who have received radiation treatment only and such reports as there are show extremely poor results Spontaneous recovery has occasionally been reported (McLaughlin et al 1979)

Table 11 Five-year survival rate for chondro sarcoma according to method of treatment.

sarcomas (Craver et al 1934) Treatment and prognosis are about the same as for reticulum-cell sarcoma (Mincey et al 1974)

2 14 5 4 *Myeloma*

The basic treatment for myeloma is cytostats radiation and surgery, combined with good general treatment (Biro 1971, Palva 1979) Surgery alone should be the treatment for solitary nodules in the limbs and extra-medullary plasma-cytoma

50 % of myeloma patients react well to cytostat treatment (Copeland 1967) The most effective cytostats are cyclophosphamide and melphalan Nitrogen mustard, which was used earlier, had a good primary effect, but its duration was limited Urethane (ethyl carbamate) has a beneficial effect on 20 % of patients and its power to prevent the growth of osteolytic tumours has been emphasized (Copeland 1967) Urethane combined with cytostats is of no avail (Copeland 1967) Cortisone reinforces the effect of urethane

Cortisone has a beneficial effect especially on older myeloma patients (Biro 1971) On the other hand, cortisone adds to the complications of myeloma, provoking especially renal insufficiency and amyloidosis (Biro 1971) 80 % of myeloma patients have neuropathy (Davis et al 1972, Dahlin 1972) Cortisone is most valuable for myeloma patients with the hyper-calcemic syndrome, in which psychopathy, wasting of the muscles, polyuria and constipation occur (Copeland 1967)

Anabolic hormones improve the patient's general condition Gammaglobulin, administered 3—4 times a month, prevents infections and helps the pat ent to recover from them (Biro 1971)

Radio-active phosphorus and fluoride are used sometimes in treating myeloma It has been discovered by means of X-rays that when treating myeloma with radioactive drugs, trabeculation is strengthened and the damage is repaired (Cook et al 1963)

The proportion of solitary myelomas is approximately 10 % (Dahlin 1964) The

with massive cytostat combinations There are no follow-up studies as yet

2 14 5 2 Reticulum-cell sarcoma

Reticulum-cell sarcoma is sensitive to radiation and it forms metastases rather late For this reason, many investigators recommend radiation as primary treatment for this type of tumour (Ulrich et al 1958, Wang et al 1968, Jack et al 1975) If radiation has no effect locally, surgical treatment is indicated (Wang et al 1968 Shoji et al 1971) A further drawback of radiation treatment is that it inactivates the resistance of the reticulum-endoteliate system and thus weakens the patient's immunity to the tumour (Miller et al 1971)

The results of surgery and radiation in the treatment of reticulum-cell sarcoma are similar some hospitals favouring the one and some the other Surgeons are in favour of radical surgery because the necrosis that follows radiation treatment causes difficulties (Boyes 1974) In any case radiation seldom succeeds in preventing the growth of a primary tumour (Dahlin 1972) High amputation has proved a successful method for treating tumours in the distal part of the femur (Boyes 1974) Post-operative radiation treatment is recommended for reticulum-cell sarcoma (Francis et al 1955)

Primary treatment of the lymph nodes is important in dealing with reticulum-cell sarcoma because the tumour easily spreads along the lymphatic ducts (Tikka et al 1969 Shoji et al 1971, Tallroth 1976) Surgery and radiation are considered to be equally effective for this (Dahlin 1972) In cases where reticulum-cell sarcoma is far advanced cytostat treatment is useful (Shoji et al 1971 Dahlin 1972)

The five-year survival rate for reticulum-cell sarcoma is approximately 50 % If the tumour is situated in the pelvic region the prognosis is worse (Shoji et al 1971)

2 14 5 3 Lympho sarcoma

Primary lympho-sarcomas of the bone account for about 10 % of all lympho-

Table 13 Five-year and ten-year survival rates for reticulum-cell sarcoma

sarcomas (Craver et al 1934) Treatment and prognosis are about the same as for reticulum-cell sarcoma (Mincey et al 1974)

2 14 5 4 Myeloma

The basic treatment for myeloma is cytostats, radiation and surgery, combined with good general treatment (Biro 1971, Palva 1979) Surgery alone should be the treatment for solitary nodules in the limbs and extra-medullary plasma-cytoma

50 % of myeloma patients react well to cytostat treatment (Copeland 1967) The most effective cytostats are *cyclophosphamide* and melphalan *Nitrogen mustard*, which was used earlier, had *a good primary* effect, but its duration *was limited* Urethane (ethyl carbamate) has a beneficial effect on 20 % of patients and its power to prevent the growth of osteolytic tumours has been emphasized (Copeland 1967) *Urethane* combined with cytostats is of no avail (Copeland 1967) Cortisone reinforces the effect of urethane

Cortisone has a beneficial effect especially on older myeloma patients (Biro 1971) On the other hand, cortisone adds to the complications of myeloma, provoking especially renal insufficiency and amyloidosis (Biro 1971) 80 % of myeloma patients have neuropathy (Davis et al 1972, Dahlin 1972) Cortisone is most *valuable* for myeloma patients with the hyper-calcemic syndrome, in which psychopathy, wasting of the muscles, polyuria and constipation occur (Copeland 1967)

Anabolic hormones improve the patient's *general condition* Gammaglobulin, administered *3—4 times* a month, prevents infections and helps the patient to recover from them (Biro 1971)

Radio-active phosphorus and fluoride are used sometimes in treating myeloma *It has* been discovered by means of X-rays *that* when treating myeloma with radioactive drugs, trabeculation is strengthened *and the* damage is repaired (Cook et al 1968)

The proportion of solitary myelomas is approximately *10 %* (Dahlin 1964) The

treatment for solitary myeloma is pre-operative radiation and radical resection (Benedict 1970, Dahlin 1972) Prognosis for solitary myeloma is good, provided there is no dissemination in the bone marrow (Cohen et al 1964) The treatment for extra-medullary plasma-cytoma is a combination of radiation and surgery (Gosepath et al 1969, Wiltshaw 1976)

In cases of myeloma, palliative surgery and radiation are very significant in the treatment of paralysis caused by pathological fractures of the spine (Martin et al 1970) Radiation should be preceded by a decompressing operation (Dahlin 1972) When a limb is fractured, intra-medullary osteo-syntheses are best used in combination with post-operative radiation treatment Prophylactic intra-medullary nailing is sometimes necessary to prevent a fracture (Koskinen 1976)

Prognosis for myeloma has been considered to be hopeless Copeland (1967) reported that in his material not a single patient had recovered from myeloma and only a few patients lived for more than five years A similar picture is given by Baldwin, et al (1967) In Dahlin s material (1972) the majority of the patients died less than two years after the appearance of the first symptoms the average period of survival being 13 months Five-year survival rates are usually under 10 % The prognosis is generally better if the disease is local It has been observed that solitary myeloma spreads after several years (Richards 1972) The prognosis for myeloma correlates poorly with radiological changes at the time of diagnosis (Gompels et al 1972)

It has been reported that myeloma develops in various different ways In young people, the disease sometimes begins gradually, the M-component is small, bone changes are peripheral, marrow smear normal — and the tumour develops slowly (Waldenstrom 1970)

Prognosis for solitary myeloma in the spine is rather good In a study comprising 55 patients (Cohen et al 1964) 33 % were still alive five years after the moment of diagnosis There have been individual cases where patients with solitary myeloma, treated with radiation, have lived as much as 30 years (Pankovich et al 1972)

The immunological distribution of myeloma is important for the prognosis In Baldwin's material (1967) the average period of survival for IgG myeloma patients was 25 3 months and for IgA myeloma patients 26 6 months In Glenchur's material (1958) prognosis was worst if electrophoresis was normal It has been reported that radiation gives best results in the treatment of IgG myeloma (Maryana 1970)

The prognosis for extra-medullary plasma-cytoma is not known exactly It is generally considered to be much better than for multiple myeloma (Gosepath et al 1969 Poole et al 1968) The location of the tumour and the degree of spreading affect the prognosis (Boyd et al 1969) After treatment late recurrence of tumours has been observed as much as 20—36 years subsequently (Gosepath et al 1969)

The immediate cause of death in myeloma patients is usually infection renal insufficiency cardiac insufficiency paralysis or haemorrhage (Martinez-Maldonado et al 1971) In myeloma patients hypertony is not associated with nephropathy (Biro 1971) Especially in the case of geriatric patients the use of contrast infusions

in X-ray studies of the kidneys of myeloma patients is contraindicated on account of irreversible changes in the kidneys (Biro 1971) In Glenchur's study of 51 terminal myeloma patients, the immediate cause of death in 17 cases was pneumonia Other infections were present in a further 29 patients

2 14 6 Vascular tumours

2 14 6 1 Angio sarcoma

Individual cases of angio-sarcoma have been treated in the same way as osteo-sarcoma (Dahlin 1972) Angio-sarcoma often causes extensive osteolytic damage and surgical treatment is often necessary on account of pathological fracture Prognosis is similar to that for osteo-sarcoma (Dahlin 1964)

2 14 6 2 Haemangio endothelioma-sarcoma

Treatment and prognosis for haemangio-endothelioma-sarcoma are the same as for osteo-sarcoma

2 14 6 3 Haemangio-pericytoma-sarcoma

Treatment and prognosis for haemangio-pericytoma-sarcoma are the same as for osteo-sarcoma

2 14 7. Connective-tissue tumours

2 14 7 1 Fibro-sarcoma

Fibro-sarcoma is a tumour that is resistant to radiation and treatment is the same as for osteo-sarcoma (Dahlin 1972) There are two types of fibro-sarcoma, secondary and medullary It is difficult to distinguish between the fibro-plastic type of osteo-sarcoma and fibrotic dysplasia (McLeod et al 1957) About 20 % of cases are secondary fibro-sarcoma, the etiology being fibrous dysplasia, Paget's disease or giant-cell tumour (Eyre-Brook et al. 1969) The prognoses for medullary and secondary fibro-sarcomas are similar to that for primary fibro-sarcoma (Gilmer et al 1958, Dahlin 1972) Some investigators consider the prognosis for fibro-sarcoma to be just as poor as that for osteo-sarcoma (Coventry et al 1957)

2 14 7.2 Lipo-sarcoma

Lipo-sarcoma is a malignant tumour, which produces early metastases in the lungs and liver. Treatment and prognosis are the same as for osteo-sarcoma (Dawson 1955, Catto et al 1963, Goldman 1964)

2 14 7 3 Malignant mesenchymoma

Malignant mesenchymoma is very rare and the tumour has features in common

Table 14 Five-year and ten-year survival rates for fibro-sarcoma

with osteo-sarcoma and lipo-sarcoma (WHO, Schajowicz et al 1972)

2 14 7 4 Primary malignant fibrous histio-cytoma

Primary malignant fibrous histiocytoma is the latest malignant bone tumour to be discovered Typical of it are extensive osteolytic damage and pathological fracture (Spanier 1977) The tumour forms early metastases like osteo-sarcoma (Spanier et al 1975)

There is as yet no clear idea about how to treat primary malignant fibrous histiocytoma Radical surgery combined with radiation treatment has been used (Spanier et al 1975, Feldmann et al 1977) This has been justified on the basis of a possible connection between this type of tumour and lympho-sarcoma or reticulum-cell sarcoma (Spanier et al 1975) Prognosis is poor In Spanier's material, the average period of survival after treatment was 21 months Slootweg et al (1977) and Webber et al (1977) report similar results Prognosis is better for a malignant fibrous histiocytoma located in soft tissue (Rantakokko 1978)

2 14 7 5 Undifferentiated sarcoma

Undifferentiated sarcoma is a little known tumour with features of osteo-sarcoma, reticulum-cell sarcoma, fibro-sarcoma and metastatic carcinoma (Schajowicz 1972)

2 14 7 6 Radiation sarcoma

Radiation sarcoma is a very malignant tumour (Schwartz et al 1958) The prognosis for a tumour that has developed in the place of a benign bone lesion is generally better than for osteo-sarcoma (Arlen et al 1971) Treatment and prognosis for radiation sarcoma are the same as for osteo-sarcoma (Steiner 1965, Mindell et al 1977)

2.14 8. Other tumours

2 14 8 1 Chordoma

Chordoma is a rare tumour It accounts for 1 5 % of all malignant bone tumours (Paavolainen et al 1976) Chordoma originates from the notochord, the remains of the notochord, or from the nuclei pulposi 10 % of chordomas produce metastases by the haematogenous route Deposits may develop in unusual locations, including the skin Recurrence may take place after many years (Dahlin 1972)

There is not complete agreement about how to treat chordoma Because the tumour grows slowly, partial resection gives years of remission and the patient is symptom-free Some chordomas are sensitive to radiation Radical surgery is seldom possible for spheno-occipital chordoma and partial resection and post-operative radiation are generally indicated (Greenwald et al 1957 Dahlin et al 1952 Paavolainen et al 1976) Surgical treatment is necessary for sacrococcygeal chordoma The prognosis for chordoma is directly related to how the tumour is treated surgically Radical excision of a spheno-occipital tumour is seldom possible Tumours in this area easily cause lethal pressure in the region of the medulla oblongata It is quite often possible to remove a sacrococcygeal chordoma by radical surgery and then the prognosis is good (Kamrin et al 1964 Rissanen et al 1967 Paavolainen et al 1976)

2 14 8.2 Adamantinoma of long bones

Adamantinoma of long bones is a rare tumour, the treatment for which is like that for osteo-sarcoma (Dockerty et al. 1942) Metastases are common after resection (Dahlin 1972)

2 14 8.3 Neuro sarcoma

Treatment for neuro-sarcoma is the same as that for osteo-sarcoma. Prognosis is only known from a few individual cases and is usually very unfavourable (Güthert 1972)

with osteo-sarcoma and lipo-sarcoma (WHO, Schajowicz et al 1972)

2 14 7 4 *Primary malignant fibrous histio cytoma*

Primary malignant fibrous histiocytoma is the latest malignant bone tumour to be discovered Typical of it are extensive osteolytic damage and pathological fracture (Spanier 1977) The tumour forms early metastases like osteo-sarcoma (Spanier et al 1975)

There is as yet no clear idea about how to treat primary malignant fibrous histiocytoma Radical surgery combined with radiation treatment has been used (Spanier et al 1975, Feldmann et al 1977) This has been justified on the basis of a possible connection between this type of tumour and lympho-sarcoma or reticulum-cell sarcoma (Spanier et al 1975) Prognosis is poor In Spanier s material the average period of survival after treatment was 21 months Slootweg et al (1977) and Webber et al (1977) report similar results Progno sis is better for a malignant fibrous histiocytoma located in soft tissue (Rantakokko 1978)

2 14 7 5 *Undifferentiated sarcoma*

Undifferentiated sarcoma is a little known tumour with features of osteo-sarcoma reticulum-cell sarcoma fibro-sarcoma and metastatic carcinoma (Schajowicz 1972)

2 14 7 6 *Radiation sarcoma*

Radiation sarcoma is a very malignant tumour (Schwartz et al 1958) The prognosis for a tumour that has developed in the place of a benign bone lesion is generally better than for osteo-sarcoma (Arlen et al 1971) Treatment and prognosis for radiation sarcoma are the same as for osteo-sarcoma (Steiner 1965, Mindell et al 1977)

2 14 8 **Other tumours**

2 14 8 1 *Chordoma*

Chordoma is a rare tumour It accounts for 1 5 % of all malignant bone tumours (Paavolainen et al 1976) Chordoma originates from the notochord the remains of the notochord, or from the nuclei pulposi 10 % of chordomas produce metastases by the haematogenous route Deposits may develop in unusual locations including the skin Recurrence may take place after many years (Dahlin 1972)

There is not complete agreement about how to treat chordoma Because the tumour grows slowly partial resection gives years of remission and the patient is symptom-free Some chordomas are sensitive to radiation Radical surgery is seldom possible for spheno-occipital chordoma and partial resection and post-operative radiation are generally indicated (Greenwald et al 1957 Dahlin et al 1952 Paavolainen et al 1976) Surgical treatment is necessary for sacrococcygeal chordoma The prognosis for chordoma is directly related to how the tumour is treated surgically Radical excision of a spheno occipital tumour is seldom possible Tumours in this area easily cause lethal pressure in the region of the medulla oblongata It is quite often possible to remove a sacrococcygeal chordoma by radical surgery and then the prognosis is good (Kamrin et al 1964 Rissanen et al 1967 Paavolainen et al 1976)

4 MATERIAL AND METHODS

The material for this study has been supplied by the Finnish Cancer Registry and consists of all primary malignant bone tumours reported between 1962 and 1968 During that period 985 cases were reported The incidence was 3 16 cases per year for 100 000 inhabitants During the same time an average of 10 958 tumours of all types were reported annually (Teppo et al 1975) Primary malignant bone tumours accounted for 1 25 % of all malignant tumours Included in the clinical follow up study were patients whose diagnoses had been confirmed by histo pathological tests, accompanied by a statement from a specialist Giant-cell tumours were considered malignant if they were found to be malignant either clinically or histo pathologically, or both Diagnosis of myeloma was considered certain if it was based on the results of histo-pathological examination or if it was supported by clinical examination, X-ray examination and laboratory findings Tumours originating in the teeth are not included in this study

The series finally comprised 869 patients whose case histories, X-rays and histo pathological samples were collected for further study

There were 86 patients (8 7 % of the original 985 cases) for whom no case history could be found and 20 (2 0 %) for whom the case histories were defective These patients were excluded from the study

Histo-pathological samples from 273 (86 4 %) sarcoma patients and 45 (8 1 %) myeloma patients were available for further study In 10 cases it was certified in the further study that a primary malignant bone tumour was not involved In 36 cases (13 2 %) the diagnosis was modified in the light of histo-pathological, clinical and X-ray examinations

Further study of the histo-pathological samples was made by Docent Tapani Sorvari at the university of Kuopio and in problematic cases assistance was also given by Professors Osmo Jarvi, Erkki Saxen, L V Ackerman and H A Sissons The author has familiarized himself with the histological study of bone tumours under the guidance of Dr Sorvari

Re-analysis of the X-rays was carried out by Professor Pekka Virtama and Dr Kalevi Katevuo, using the computer-assisted diagnosis developed by Lodwick

Information about survival was checked personally in hospitals, church registers and in documents provided by the Finnish Central Office for Statistics The follow-up period varied from six years to eleven years, eleven months (average 6 1/2 years) The follow-up ended on 31 12 1974

Surgical intervention was considered to be radical if amputation or resection allowed a distance of 5 cm from the di-

3. PURPOSE OF THE STUDY

The purpose of the study is to clarify the clinical picture, methods of treatment and follow-up results, of primary malignant bone tumour and to attempt an answer to the following questions:

- How common are primary malignant bone tumours in Finland?
- What symptoms do bone tumour patients have and what are the findings?
- Where are the tumours located?
- What is the treatment to be given?
- What is the prognosis?

4 MATERIAL AND METHODS

The material for this study has been supplied by the Finnish Cancer Registry and consists of all primary malignant bone tumours reported between 1962 and 1968 During that period 985 cases were reported The incidence was 3 16 cases per year for 100 000 inhabitants During the same time an average of 10,958 tumours of all types were reported annually (Teppo et al. 1975) Primary malignant bone tumours accounted for 1 25 % of all malignant tumours Included in the clinical follow-up study were patients whose diagnoses had been confirmed by histo-pathological tests, accompanied by a statement from a specialist Giant-cell tumours were considered malignant if they were found to be malignant either clinically or histo-pathologically, or both Diagnosis of myeloma was considered certain if it was based on the results of histo-pathological examination or if it was supported by clinical examination, X-ray examination and laboratory findings Tumours originating in the teeth are not *included in this study*

The series finally comprised 869 patients whose case histories, X-rays and histo-pathological samples were collected for further study

There were 86 patients (8 7 % of the original 985 cases) for whom no case history could be found and 20 (2 0 %) for whom the case histories were defective *These patients were excluded from the study*

Histo-pathological samples from 273 (86 4 %) sarcoma patients and 45 (8 1 %) myeloma patients were available for further study In 10 cases it was certified in the further study that a primary malignant bone tumour was not involved In 36 cases (13 2 %) the diagnosis was modified in the light of histo-pathological, clinical and X-ray examinations

Further study of the histo-pathological samples was made by Docent Tapani Sorvari at the university of Kuopio and in problematic cases assistance was also given by Professors Osmo Järvi, Erkki Saxen, L V Ackerman and H A Sissons The author has familiarized himself with the histological study of bone tumours under the guidance of Dr Sorvari

Re-analysis of the X-rays was carried out by Professor Pekka Virtama and Dr Kalevi Katevuo, using the computer-assisted diagnosis developed by Lodwick

Information about survival was checked personally in hospitals, church registers and in documents provided by the Finnish Central Office for Statistics The follow-up period varied from six years to eleven years eleven months (average 6 ½ years) The follow-up ended on 31 12 1974

Surgical intervention was considered to be radical if amputation or resection allowed a distance of [redacted] cm from the di-

3. PURPOSE OF THE STUDY

The purpose of the study is to clarify the clinical picture, methods of treatment and follow-up results, of primary malignant bone tumour and to attempt an answer to the following questions

- How common are primary malignant bone tumours in Finland?
- What symptoms do bone tumour patients have and what are the findings?
- Where are the tumours located?
- What is the treatment to be given?
- What is the prognosis?

5. RESULTS

5 1 INCIDENCE, AGE AND SEX DISTRIBUTION

The clinical study comprised 869 patients suffering from primary malignant bone tumour Incidence was 2 7 new cases per 10^5 inhabitants annually The average age of the patients was 54 7 years, the youngest being two years old and the oldest 93 82 5 % of the patients were over 40 and there were 442 men (50 9 %) and 427 women (49 1 %)

5 2 HISTOLOGICAL DISTRIBUTION

There were 21 different histological types of tumour It was possible by means of electrophoresis to classify 494 (89 3 %) of the 553 myeloma patients into immunological sub-groups (Table 15). Of the myeloma patients 262 (47 4 %) were male and 291 (52 6 %) were female Of the remaining patients, i e those with sarcoma, 180 (57 0 %) were male and 136 (43 0 %) were female In the case of 18 sarcoma patients, the sample was too small or too badly preserved for it to be possible to classify it in further study, but it was nevertheless possible to confirm that sarcoma was involved Histological age distribution is shown in Figs 21—35

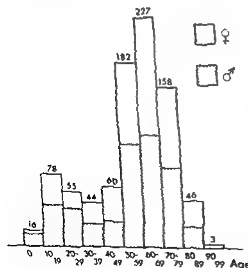

Figure 1 Age distribution of 869 patients with primary malignant bone tumour

5 3 SYMPTOMS AND DIAGNOSIS

5.3.1. Pain

Pain is the most common symptom of malignant bone tumours 280 (88[illegible] %) of the sarcoma patients and 511 (92 4 %) of the myeloma patients experienced pain at the place of the tumour In 566 cases (71 6 %) it was considered to be referred pain or neurological pain

5.3 2 Size of tumours and resistance to palpation

In sarcoma patients tumours were on the average 6 0 cm in diameter.

There was a palpable tumour in 260 patients (29 9 %), 209 (66 1 %) of whom were

seased tissue It was considered to be local if the distance was less than 5 cm Biopsy was not considered to be part of treatment

The histological classification of tumours according to their degree of malignancy was made on the basis of the recommendations published by the World Health Organization in 1972, together with a complementary classification of additional tumours, drawn up by Docent Tapani Sorvari

Crude survival of patients was calculated by means of the so-called actuary technique (Cutler et al 1958) This procedure makes it possible to include all the information available, regardless of the length of the follow-up time In order to eliminate the part played by the normal mortality rate, the figure obtained for crude survival was compared with the normal mortality rate for a population of the same age The latter was calculated from tables supplied by the Central Office for Statistics The relationship between the two figures is called age-corrected or relative survival (Ederer et al 1961)

The normal laboratory values were based on Laboratoriotutkimusten vertailuarvoja by Leskinen et al 1972

Statistical significance was calculated by the Mantel-Haenszel method

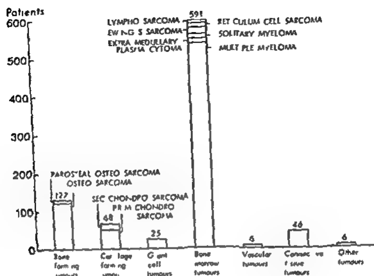

Figure 2 Histological distribution of 869 primary malignant bone tumours

sarcoma patients and 51 (9 2 %) myeloma patients

5 3 3 Pathological fracture

There was pathological fracture in 310 patients (35 7 %) Of these 58 (18 4 %) were sarcoma patients and 252 (79 5 %) were myeloma patients

5.3 4 Deterioration of general health

Deterioration of general health was a symptom in ^{4}91 patients (56 4 %) of whom 41 (13 0 %) were sarcoma patients and 450 (81 4 %) were myeloma patients 28 (8 9 %) of the sarcoma patients and 380 (43 7 %) of the myeloma patients reported that they had lost weight

5 3 5 Trauma in anamnesis

Only 7 patients (0 8 %) reported certain trauma in the region of the tumour Of these there was one sarcoma patient who had chondro-sarcoma

5 3 6 General symptoms

Slight fever was a symptom in 9 (2 8 %) of the sarcoma patients and 90 (16 3 %) of the myeloma patients Local inflammation occurred in 12 (3 8 %) of the sarcoma patients and in 130 (23 %) of the myeloma patients Oedema at the site of the tumour was a symptom in 234 patients (26 9 %), of whom 106 (33 5 %) were sarcoma patients and 128 (23 1 %) myeloma patients Haemorrhage was a symptom in 87 patients (10 0 %) 2 of whom (0 6 %) were sarcoma patients and 85 (15 4 %) myeloma patients

5 3 7 Lack of symptoms

There were 12 patients (1 4 %) who had no symptoms Two of these had primary chondro-sarcoma one had secondary chondro-sarcoma and one had chordoma Four multiple myeloma patients and two extra-medullary plasma-cytoma patients had no symptoms

5.3.8. Duration of symptoms

The average duration of symptoms before diagnosis was 7.2 months. Symptoms had lasted for less than six months in patients with *osteo-sarcoma*, *reticulum-cell sarcoma*, *lympho-sarcoma*, *fibro-sarcoma*, *primary fibrous histio-cytoma*, also in cases of *myeloma* (with the exception of solitary myeloma) and *extra-medullary plasma-cytoma*. Symptoms had lasted longer in patients with *parosteal osteo-sarcoma* (15.3

velopment of primary malignant bone tumours, neither could it be proved that trauma had anything to do with the growth of the tumour. Radiation sarcoma was confirmed in two female patients One of these had been given radiation treatment for tuberculosis of the knee and the other had had radiation treatment in the humerus radiation sarcoma subsequently developed at these sites There was one case where fibro-sarcoma had developed as a result of Paget's disease

5 5 LOCATION

The location of tumours is shown in Table 16 and Figures 21—35 Extra-medullary plasma-cytoma was in five patients located in the nose, in two patients in the hypo-pharynx, in one in the sinus maxillaris, there was also one case where the tumour was in the orbit and another in which it was situated in the inguinal nodule

5 6 DISCUSSION

The 10[5] incidence of primary malignant bone tumours was 2 84 new tumours annually and bone tumours accounted for 1 28 % of all malignant tumours These figures correspond roughly to those published elsewhere (Swedish Cancer Registry 1960, The Cancer Registry of Norway 1964, Copeland 1967, Bristol Registry 1971)

Histological distribution was similar to that in earlier studies There were no cases of the following rare tumours juxta-cortical chondro-sarcoma, mesenchymal chondro-sarcoma, lipo-sarcoma, malignant mesenchymoma, undifferentiated sarcoma and adamantinoma of long bones The Finnish classification , included also secondary chondro-sarcoma, solitary myeloma, extra-medullary plasma-cytoma, haemangio-pericytoma-sarcoma, radiation sarcoma, primary malignant fibrous histio-cytoma, NUD sarcoma, fibrolipo-myxoma malignum, chondro-myxoma malignum and fibro-myxoma malignum

Pain was the most common symptom and it occurred in 88 % of the patients It was at first considered to be neurological or referred pain in 71 6 % of the patients It was not possible in the present study to show that trauma played any part in the etiology of primary malignant bone tumours Symptoms, on the whole, had lasted rather a short time when the diagnosis was made, 7 2 months on the average Diagnosis was delayed in only three cases

5 7 X-RAY FINDINGS

5 7.1. Plain radiography

Plain radiography was carried out before treatment on 816 patients (93 9 %) in order to discover whether there were changes in the bone In 746 cases (91 4 %) the result of this examination was concordant with the presence of malignant tumour The X-ray was interpreted as normal in 70 cases (8 6 %) Of the sarcoma patients 290 (97 6 %) were found in the X-ray examination to have symptoms concordant with malignant bone tumour The corresponding figures for myeloma patients were 456 (87 9 %)

5.7 2. Angiography

Angiography was performed on 60 patients (6 9 %) The result of the examina-

5 7 X-RAY FINDINGS

5 7 1 Plain radiography

Plain radiography was carried out before treatment on 816 patients (93 9 %) in order to discover whether there were changes in the bone In 746 cases (91 4 %) the result of this examination was concordant with the presence of malignant tumour The X-ray was interpreted as normal in 70 cases (8 6 %) Of the sarcoma patients 290 (97 6 %) were found in the X-ray examination to have symptoms concordant with malignant bone tumour The corresponding figures for myeloma patients were 456 (87 9 %)

5 7 2 Angiography

Angiography was performed on 60 patients (6 9 %) The result of the examina-

loma patients (87 9 %) 56 of these patients (11 5 %) came for a further examination

5 8.3 Study of frozen sections

Study of frozen sections was carried out on 41 sarcoma patients in connection with surgery In six cases (14 [illegible] %) the tumour was considered to be benign in the light of this study In the remaining 35 cases (85 4 %) the study of frozen sections revealed the presence of malignant tissue

5 8 4 Confirmation of diagnosis

Diagnosis was considered to be confirmed if the result of the histo-pathological examination was certain In cases of myeloma, the diagnosis was considered to be confirmed if there was either a clear histo-pathological diagnosis or if X-ray findings and laboratory findings, together with the clinical picture, were concordant with such a diagnosis Only a few marrow smears were available for the present study, because haematological laboratories do not keep such samples for long

5 8 5 Discussion

A frozen section taken during surgery may sometimes be helpful, but generally the diagnosis should be made before surgery [illegible] embarked upon, radiologically and with the aid of histological examination of adequate biopsy specimens In the present series a frozen section was examined in 41 cases and malignancy was confirmed in 85 4 % of these cases

5 9 LABORATORY TESTS

Laboratory findings are shown in Figure 3

Table 18 SR values for 850 sarcoma and myeloma patients

SR mm/h	Sarcoma patients %	Myeloma patients %
1—19	49 4	5.5

5 9 1. Discussion

Laboratory findings are important in diagnosing primary malignant bone tumours and especially when studying the degree of spreading The laboratory tests required in the diagnosis of bone sarcomas are very simple and are easy to carry out in any hospital In the present study, the blood group distribution was approximately the same as in the study by Nevanlinna (1973)

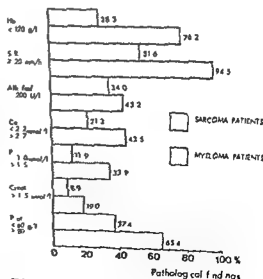

Figure 3 Pathological laboratory findings (%) for sarcoma and myeloma patients

tion was concordant with the presence of malignant bone tumour in 47 of the sarcoma patients (87 0 %) For myeloma patients the figure was 33 3 %

5 7 3 Lymphography

Lymphography was performed on 5 patients (0 6 %) The examination showed that the tumour had spread into the lymphatic ducts in one (25 %) of the sarcoma patients Lymphography was performed on one myeloma patient who was suffering from extra-medullary plasma-cytoma and it was found that the tumour had reached the lymph nodes

5 7 4 Other examinations

Scintigraphy was performed on 26 patients (3 0 %) It was found in 13 (76 5 %) of the patients with sarcoma that isotope had collected in the bone at the place revealed in the X-ray examination In all the nine myeloma patients examined it was found that isotope had collected

Tomography was performed on 122 patients (14 3 %) and the result was concordant with the presence of primary malignant bone tumour in 68 of the 69 sarcoma patients (98 6 %) For myeloma patients 48 of 53 examinations (90 6 %) were positive

Neither computer tomography nor thermography were performed for the present study

5 7 5 Discussion

The final radiological diagnosis was possible when using ordinary radiographs in 91 4 % of cases which is in accord with findings reported elsewhere (Lodwick 1967 Ranke 1968)

Angiography was usually helpful for determining the extent of the tumour outside the bone involved Angiography may also be helpful for differentiating chondrosarcoma from benign osteo-chondroma but in general it does not seen to help when trying to distinguish between benign and malignant bone lesions (Yaghmai 1979) It is valuable in preoperative planning particularly in the case of malignant tumours of the pelvis

Scintigraphy is an important method for revealing primary malignant bone tumours Because the series studied consists of cases in the nineteen-sixties scintigraphy was used in only 26 cases No conclusions concerning its value can therefore be drawn It does however seem to be of great value for detecting local bone marrow and distant metastases It is very useful in postoperative follow-up

The significance of lymphography is widely recognized and it is used increasingly in planning treatment for primary malignant bone tumours

5 8 HISTO PATHOLOGICAL EXAMINATION AND CONFIRMATION OF DIAGNOSIS

5 8 1 Sarcoma patients

A histological diagnosis of every sarcoma patient in the present study was supplied by an expert pathologist Samples from 261 patients (82 3 %) were available for this study

5 8 2 Myeloma patients

A diagnosis by a specialist either histopathological or on the basis of a marrow smear was supplied for 486 of the mye

5 10 TREATMENT

Treatment of patients is shown in Tables 19 and 20 and also in appendix 9 2 Of the osteo-sarcoma patients, 74 (60 2 %) were treated by means of radical surgery It proved possible to treat 30 (44 1 %) of the chondro-sarcoma patients by means of radical surgery The corresponding figure for giant-cell tumours was 10 (40 0 %) Of the Ewing s-sarcoma patients it was possible to treat six (33 3 %) by means of radical surgery In the case of other tumours, radical surgery was less frequent

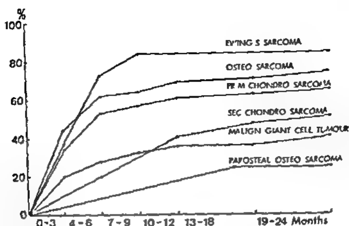

Figure 4 The development of metastases as a function of time, in osteo-sarcoma, parosteal osteo-sarcoma, primary and secondary chondro-sarcoma, malignant giant-cell tumour and Ewing s sarcoma.

were given cytostat treatment, 131 (24 6 %) received radiation treatment and 28 (5 3 %) other treatment 130 (24 4 %) of these patients received basic treatment

In the present study the radiation referred to [illegible] roentgen therapy, only very few patients received megavolt therapy The radiation dose was 200 rad per day For Ewing s sarcoma the dose was 5 500—8,200 rad., for reticulum-cell sarcoma 2,400—6,800 rad and for lympho-sarcoma 4,000—6,000 rad

The cytostatic agents used were cyclophosphamide, methotrexate, melphalan and ethyl carbamate Treatment with massive doses of three or four different cytostatic agents was not used

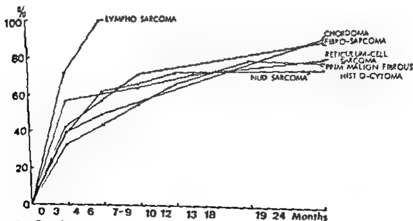

Figure 5 Development of metastases, in reticulum-cell sarcoma, fibro-sarcoma, chordoma, malignant fibrous histio-cytoma and NUD sarcoma.

5 11 PROGNOSIS

5 11 1. Metastases

More than 50 % of sarcoma patients had metastases within six months of presenting themselves for treatment, with the exception of those suffering from secondary chondro-sarcoma, for whom the figure was 40 % and those suffering from malignant giant-cell tumours, for whom the figure was 32 % Metastases were rather rare after one year (Figures 4 and 5)

5 11 1 1 Discussion

Metastases of primary malignant bone tumours develop rapidly by the haemathogeneous route, most frequently in the lungs, liver, organs of the abdominal cavity and more rarely in the lymphatic ducts (Sellors 1970, Beck et al 1976, Tallroth 1976) The realization that metastases form quickly has led to the use of modern combined cytostat treatment for many primary malignant bone tumours

5 11.2 Survival

5 11 2 1 Bone-forming tumours

5 11 2 1 1 Osteo sarcoma

The 5-year survival rate for osteo-sarcoma was 28 4 % and the 10-year survival rate was 24 8 %

The 5-year survival rate for patients with osteo-sarcoma in the humerus was 7 7 % Only one patient lived more than five years, this patient had a tumour in the diaphysis of the humerus, which was treated by extirpation and post-operative radiation

For osteo-sarcoma patients whose tumour was in the femur, the 5-year survival rate was 27 3 % The location of the tumour has considerable significance Prognosis is better if a tumour is situated in the distal part of the bone Of those patients who had tumours in the collum or trocanter region of the femur, not one lived for five years All those patients with osteo-sarcoma in the femur who lived more than five years, were treated by means of radical amputation

The prognosis for osteo-sarcoma in the tibia is better than for osteo-sarcoma in the other long bones The 5-year survival rate was 45 0 % and the 10-year survival rate was 40 0 % With one exception, all those patients who lived for more than five years were treated by means of radical ablative surgery

The results of treatment when the tumour was in the fibula or radius correspond approximately to the above

Prognosis was poor for osteo-sarcoma patients if the tumour was located elsewhere than in the long bones No patient with a tumour in the scapula lived as long as five years and the average period of survival from the moment of diagnosis was 1 1 years For patients with osteo-sarcoma in the ribs the prognosis was even worse none surviving longer than 0 4 years

The prognosis for osteo-sarcoma if the tumour is in the pelvis or the spine is poor because radical excision of the tumour is seldom possible

Prognosis was good for the four patients who had osteo-sarcoma in the maxilla All these tumours were treated by means of radical resection and radiation all the patients have survived for more than five years and are still symptom-free

Table 21 Survival rate for 869 patients suffering from primary malignant bone tumours (crude survival)

5 11 PROGNOSIS

5 11.1. Metastases

More than 50 % of sarcoma patients had metastases within six months of presenting themselves for treatment, with the exception of those suffering from secondary *chondro-sarcoma, for whom the figure was* 40 % and those suffering from malignant giant-cell tumours, for whom the figure was 32 % Metastases were rather rare after one year (Figures 4 and 5)

5 11 1 1 Discussion

Metastases of primary malignant bone tumours develop rapidly by the haemathogeneous route, most frequently in the lungs, liver, organs of the abdominal cavity and more rarely in the lymphatic ducts (Sellors 1970, Beck et al 1976, Tallroth 1976) The realization that metastases form quickly has led to the use of modern combined cytostat treatment for many primary malignant bone tumours

5 11 2 Survival

5 11 2 1 Bone-forming tumours

5 11 2 1 1 Osteo-sarcoma

The 5-year survival rate for osteo-sarcoma was 28 4 % and the 10-year survival rate was 24 8 %

The 5-year survival rate for patients with osteo-sarcoma in the humerus was 7 7 % Only one patient lived more than five years, this patient had a tumour in the diaphysis of the humerus which was treated by extirpation and post-operative radiation

For osteo-sarcoma patients whose tumour was in the femur, the 5-year survival rate was 27 3 % The location of the tumour has considerable significance Prognosis is better if a tumour is situated in the distal part of the bone Of those patients who had tumours in the collum or trocanter region of the femur, not one *lived for five years All those patients* with osteo-sarcoma in the femur who lived more than five years, were treated by means of radical amputation

The prognosis for osteo-sarcoma in the tibia is better than for osteo-sarcoma in the other long bones The 5-year survival *rate was 45 0 % and the 10-year survival* rate was 40 0 % With one exception all those patients who lived for more than five years were treated by means of radical ablative surgery

The results of treatment when the tumour was in the fibula or radius correspond approximately to the above

Prognosis was poor for osteo-sarcoma patients if the tumour was located elsewhere than in the long bones No patient with a tumour in the scapula lived as long as five years and the average period of survival from the moment of diagnosis was 1 1 years For patients with osteo-sarcoma in the ribs the prognosis was even worse none surviving longer than 0 4 years

The prognosis for osteo-sarcoma if the tumour is in the pelvis or the spine is poor, because radical excision of the tumour is seldom possible

Prognosis was good for the four patients who had osteo-sarcoma in the maxilla All these tumours were treated by means of radical resection and radiation all the patients have survived for more than five years and are still symptom-free

been developed when the patients in this study were being treated. With three exception all those patients with osteosarcoma in long bones who survived for more than five years were treated by means of ablative surgery

The five-year survival rate was particularly bad for patients who had a tumour elsewhere than in long bones The prognosis in this study for patients with tumours in the scapula, ribs, spine or skull is worse than in the report by Dahlin (1972) The results of treatment for tumours in the mandibula were equally bad and deviated from the results generally reported elsewhere (Garrington et al 1967)

According to the findings of the present study it is possible by means of radiation to slow down the growth of a tumour and prolong the period of survival It was impossible to determine the exact dose of radiation that had been given to each patient.

The prognosis for parosteal osteo-sarcoma ■ better than for any other primary malignant bone tumour The three patients in this study with parosteal osteosarcoma, lived for more than ten years This result compares favourably with those in other reports All these patients were treated surgically

5 11 2.2 *Cartilage-forming tumours*

5 11 2 2 1 *Primary chondro-sarcoma*

The five-year survival rate for primary chondro-sarcoma was 35 8 % and the 10-year survival rate 27 3 %

The five-year survival rate for patients who had tumours in the femur was 14 3 % The prognosis for those with tumours in the tibia was the same Those patients with chondro-sarcoma in long bones who lived more than five years were treated with radical surgery One patient with chondro sarcoma in the pelvis who lived more than ten years, underwent hemipelvectomy Four of the 11 patients with chondro-sarcoma in the pelvis were treated with radiation and they lived for more than five years

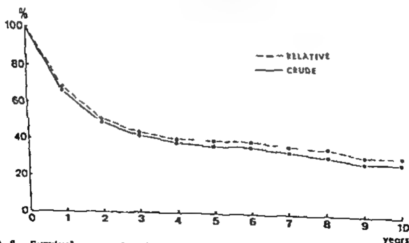

Figure 8 Survival curves for those suffering from primary chondro-sarcoma 53 patients (relative and crude survival)

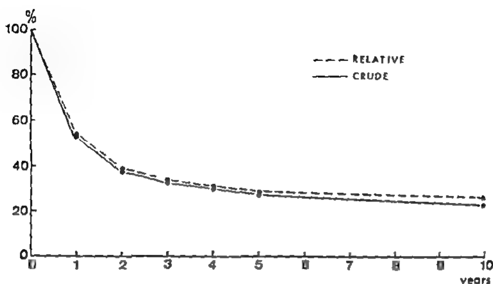

Figure 6 Survival curves for those suffering from osteo-sarcoma, 123 patients (relative and crude survival)

The longest period of survival for a patient with osteo-sarcoma in the mandibula was 12 years

5 11 2 1 2 *Parosteal osteo-sarcoma*

The 5-year and 10-year survival rates for parosteal osteo-sarcoma were 75 %.

5 11 2 1 3 *Discussion*

The common treatment for osteo-sarcoma in long bones is radical ablative surgery 64 patients (73 6 %) with osteo-sarcoma in long bones were treated by means of radical amputation or ex-articulation Massive cytostat treatment had not yet

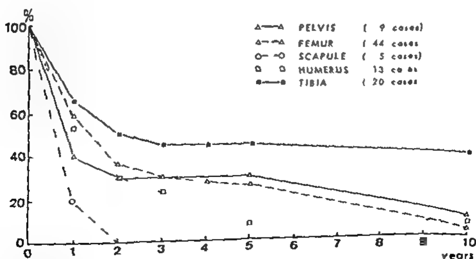

Figure 7 Survival curves for osteo-sarcoma patients with tumours in the scapula pelvis and femur (crude survival)

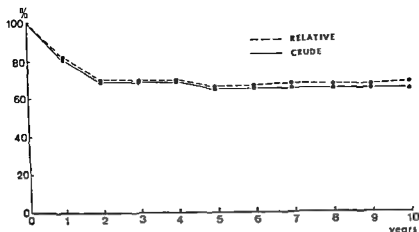

Figure 10 Survival curves for those suffering from malignant giant-cell tumours, 25 patients (relative and crude survival)

It is typical of Ewing's sarcoma that it develops early metastases and the prognosis is poor In the present series, distant metastases developed within nine months in all certified cases Prognosis was best if the tumour was in the tibia, the average survival period for such cases being 1 7 years Three patients lived for over five years One with a tumour in the caput humeri, was treated with radical radiation The other two had tumours in the femur in one case the tumour was in the distal metaphysis and that patient underwent hemipelvectomy, the other patient had a tumour in the diaphysis and the treatment was amputation These results are comparable with what has been reported earlier (McCormack et al 1952,

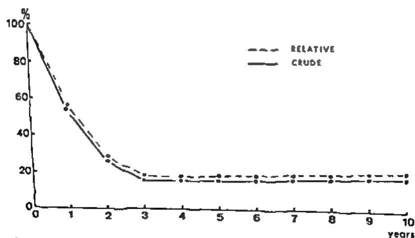

Figure 11 Survival curves for those suffering from Ewing s sarcoma, 18 patients (relative and crude survival)

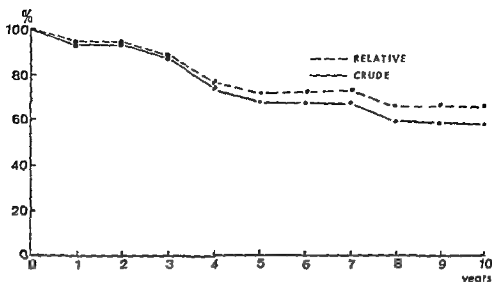

Figure 9 Survival curves for those suffering from secondary chondro-sarcoma, 15 patient (relative and crude survival))

5 11 2 2 2 Secondary chondro-sarcoma

The five-year survival rate for secondary chondro-sarcoma was 66 7 % and the ten-year survival rate was 58 8 %

Ten patients survived for more than five years All of these had undergone surgery, four of them radical surgery

5 11 2 2 3 Discussion

In the present study the prognosis for primary chondro-sarcoma was the same as for osteo-sarcoma, although it has generally been considered better (Dahlin 1972) The prognosis for secondary chondro-sarcoma is twice as good as that for primary chondro-sarcoma The general idea seems to be that the results of treatment for secondary chondro-sarcoma are good in a short term follow-up, but bad in a long term follow-up (Lindbom et al 1961, Dahlin 1972) This concept is not borne out by the results of the present study Our findings suggest that in certain cases it may be worth considering whether, instead of radical ablative surgery one may not use a less disabling surgical intervention

5 11 2 3 Giant-cell tumours

5 11 2 3 1 Malignant giant-cell tumour

The five-year survival rate for malignant giant-cell tumours was 64 0 % and the ten-year survival rate was the same

5 11 2 3 2 Discussion

The prognosis for malignant giant-cell tumours is good, if the primary treatment is radical (Dahlin 1972, Koskinen 1978) The present study showed that in some cases conservative surgical treatment was possible Late metastases, even after ten years, sometimes occur

5 11 2 4 Bone-marrow tumours

5 11 2 4 1 Ewing's sarcoma

Both the five-year and ten-year survival rates for Ewing's sarcoma were 16 6 %

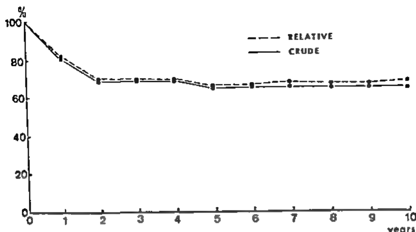

Figure 10 Survival curves for those suffering from malignant giant-cell tumours, 25 patients (relative and crude survival)

It is typical of Ewing's sarcoma that it develops early metastases and the prognosis is poor In the present series, distant metastases developed within nine months in all certified cases Prognosis was best if the tumour was in the tibia, the average survival period for such cases being 1 7 years Three patients lived for over five years One with a tumour in the caput humeri, was treated with radical radiation The other two had tumours in the femur in one case the tumour was in the distal metaphysis and that patient underwent hemipelvectomy, the other patient had a tumour in the diaphysis and the treatment was amputation These results are comparable with what has been reported earlier (McCormack et al 1952,

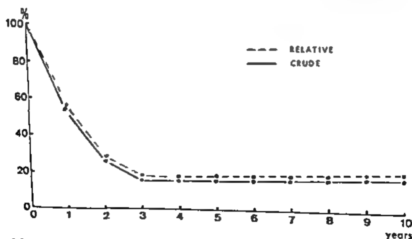

Figure 11 Survival curves for those suffering from Ewing's sarcoma, III patients (relative and crude survival)

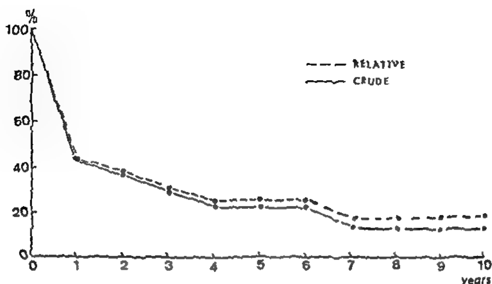

Figure 12 Survival curves for those suffering from reticulum-cell sarcoma, 14 patients (relative and crude survival)

Wang 1953, Phelan et al 1964, Phillips et al 1967, Dahlin 1972)

5 11 2 4 2 Reticulum-cell sarcoma

The 5-year survival rate for reticulum-cell sarcoma was 21 5 % and the 10-year survival rate was 12 9 %

Three patients who lived more than five years were treated with radiation and with a combination of radiation and cytostats In two cases the tumour was located in the femur and in one in the spine

5 11 2 4 3 Lympho-sarcoma

The five-year and ten-year survival rates for lympho-sarcoma were 0 % Not a single patient lived as long as two years from the moment of diagnosis

The treatment of patients suffering from

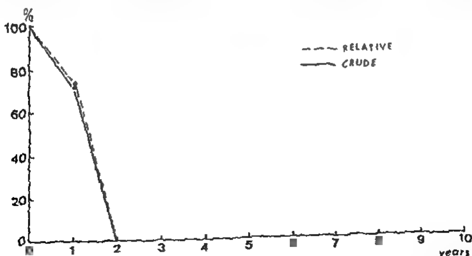

Figure 13 Survival curves for those suffering from lympho-sarcoma 6 patients (relative and crude survival)

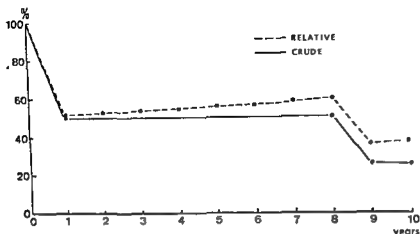

Figure 14 Survival curves for those suffering from solitary myeloma, 10 patients (relative and crude survival)

lympho-sarcoma did not differ from that for patients with reticulum-cell sarcoma, but the prognosis was worse

5 11 2 4 4 *Solitary myeloma*

The five-year survival rate for solitary myeloma were 50 0 % and the ten-year survival rate was 25 0 %

Four of the five solitary myeloma patients who lived for more than five years were given radiation treatment Two of them underwent palliative surgery One patient was given anabolic hormones

5 11 2 4 5 *Multiple myeloma*

The five-year survival rate for patients suffering from multiple myeloma was 4 8 % and the ten-year survival rate was 3 0 %

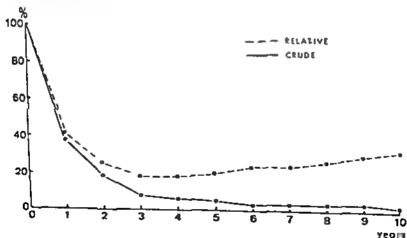

Figure 15 Survival curves for those suffering from multiple myeloma, 533 patients (relative and crude survival)

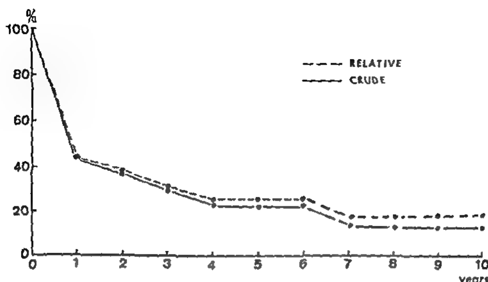

Figure 12 Survival curves for those suffering from reticulum-cell sarcoma, 14 patients (relative and crude survival)

Wang 1953, Phelan et al 1964, Phillips et al 1967, Dahlin 1972)

5 11 2 4 2 Reticulum-cell sarcoma

The 5-year survival rate for reticulum-cell sarcoma was 21 5 % and the 10-year survival rate was 12 9 %

Three patients who lived more than five years were treated with radiation and with a combination of radiation and cytostats In two cases the tumour was located in the femur and in one in the spine

5 11 2 4 3 Lympho-sarcoma

The five-year and ten-year survival rates for lympho-sarcoma were 0 % Not a single patient lived as long as two years from the moment of diagnosis

The treatment of patients suffering from

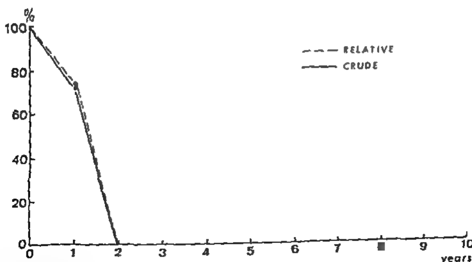

Figure 13 Survival curves for those suffering from lympho-sarcoma, 6 patients (relative and crude survival)

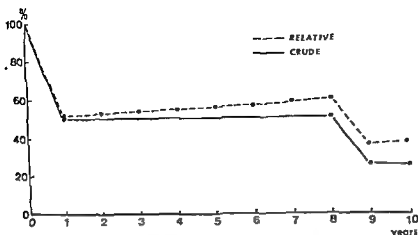

Figure 14 Survival curves for those suffering from solitary myeloma, III patients (relative and crude survival)

lympho-sarcoma did not differ from that for patients with reticulum-cell sarcoma, but the prognosis was worse

5 11 2 4 4 Solitary myeloma

The five-year survival rate for solitary myeloma were 50 0 % and the ten-year survival rate was 25 0 %

Four of the five solitary myeloma patients who lived for more than five years were given radiation treatment Two of them underwent palliative surgery One patient was given anabolic hormones

5 11.2 4 5 Multiple myeloma

The five-year survival rate for patients suffering from multiple myeloma was 4 8 % and the ten-year survival rate was 3 0 %

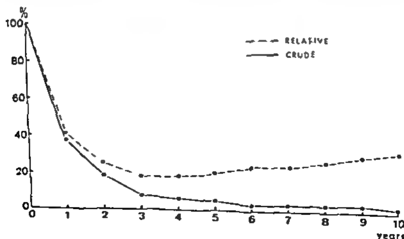

Figure 15 Survival curves for those suffering from multiple myeloma, 533 patients (relative and crude survival)

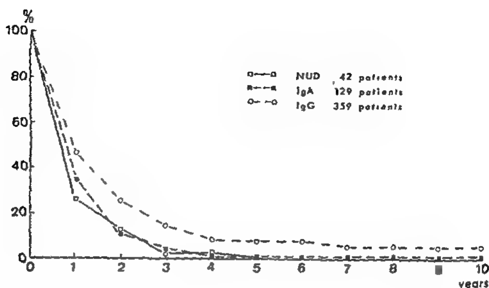

Figure 16 Survival curves for patients suffering from multiple myeloma types NUD, I[g]A and IgG (crude survival)

Of those patients suffering from multiple myeloma, 131 (24 6 %) were given cytostat treatment and the five-year survival rate was 7 6 % 90 patients (16 9 %) received cytostat and radiation treatment, the five-year survival rate being 4 4 % 78 patients (14 6 %) received cytostat and cortisone treatment, the five-year survival rate being 3 8 % Of those patients who received radiation, cortisone, urethane, anabolic hormone and radio-active fluoride treatment or a combination of these, not one lived for five years Of the 130 patients (24 4 %) who received basic treatment two patients lived more than five years

The average survival periods were 0 7 years for the NUD type, 0 8 years for the IgA type, 1 1 years for the IgG type and 0 9 years for the IgM type If we compare different methods of treatment, the average period of survival when a combination of cytostat and radiation treatment was used was 1 ■ years, for cases of IgG myeloma the average period of survival when radiation and cortisone treatment were combined was 1 9 years However, these figures are not statistically signi[fi]cant owing to the small number of pat[i]ents involved (9) With all other metho[ds] of treatment, the average period of surv[i]val was less than one year

5 11 2 4 6 Extra-medullary plasma-cytoma

The five-year survival rate for patien[ts] suffering from extra-medullary plasma[-]cytoma was 60 % and the ten-year surviva[l] rate was 30 0 %

Two of the six extra-medullary plas[-]ma-cytoma patients who lived for ove[r] five years had been treated surgically an[d] with radiation Two patients were give[n] radiation treatment and one was treate[d] by means of surgical extirpation

5 11 2 4 7 Discussion

In the present study the five-year survival rate for Ewing's sarcoma corresponded approximately to that reported by other investigators The basis of present experimental treatment is massive cytostat treatment, ■ combination of three or four

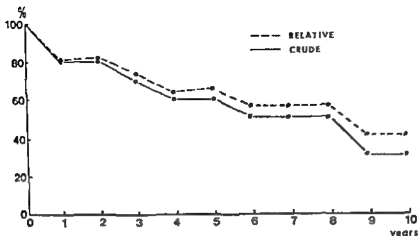

Figure 17 Survival curves for those suffering from extra-medullary plasma-cytoma, 10 patients (relative and crude survival)

drugs, plus surgical and radiation treatment (Jenkin et al 1976) No other form of treatment is possible, because in this disease micro-metastases develop early There are as yet no published reports of a long term follow-up of patients treated in this way

The results of treatment for reticulum-cell sarcoma were clearly worse in this study than in most other reports The average period of survival was 1 5 years Only three of the 14 reticulum-cell sarcoma patients lived more than five years Two patients had a tumour in the femur and were treated with radiation one of them was also given cytostat treatment which has been found effective by other investigators (Shoji et al 1971 Dahlin 1972)

In the present study the prognosis for lympho-sarcoma, unlike that in other reports (Mincey et al 1974), was exceptionally bad

For myeloma both the treatment given and the prognosis corresponded exactly with what has been reported elsewhere In treating solitary myeloma a combination of surgery and radiation gave good results, which corresponds with the picture given by other investigators (Gosepath et al 1969) The results of treatment for multiple myeloma are very poor and the average period of survival as from the moment of diagnosis was less than one year This is about the same as reported elsewhere (Carson et al 1955, Baldwin, et al 1967, Dahlin 1972)

The prognosis for extra-medullary plasma-cytoma is good if the location and spread of the tumour allow radical treatment to be undertaken (Poole et al 1968) In the present study, the five-year survival rate was 60 0 % The ten-year survival rate was only 30 0 % however, which is in keeping with the finding that late metastases are common with extra medullary plasma-cytoma (Gosepath et al 1969)

5 11 2 5 *Vascular tumours*

5 11 2 5 1 *Angio sarcoma*

Of the four patients suffering from angio-sarcoma one lived for over five years

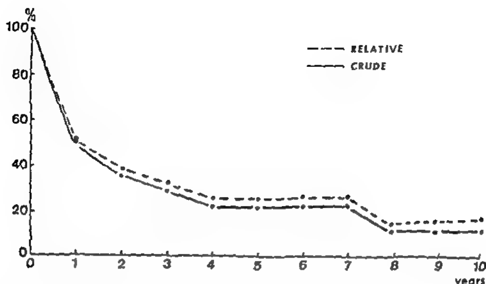

Figure 18 Survival curves for those suffering from fibro-sarcoma, 14 patients (relative and crude survival)

5 11 2 5 2 Haemangio-pericytoma-sarcoma

Neither of the two patients suffering from haemangio-pericytoma-sarcoma lived as much as five years

5 11 2 5 3 Discussion

The prognosis for angio-sarcoma and haemangio-pericytoma-sarcoma cannot be established with any certainty on account of the rarity of these tumours The treatment recommended follows the same principles as that for osteo-sarcoma (Dahlin 1972) In the light of the individual cases in the present study it may be said that the tumours are rather malignant Prognosis is very poor

5 11 2 6 Other connective-tissue tumours

5 11 2 6 1 *Fibro-sarcoma*

The 5-year survival rate for patients suffering from fibro-sarcoma was 21 5 % and the ten-year survival rate was 10 8 %

All the fibro-sarcoma patients who lived for more than five years were treated by means of radical surgery and radiation One tumour located in the mandibula was treated by means of local evacuation and radiation

5 11 2 6 2 Primary malignant fibrous histio-cytoma

The five-year survival rate for patients suffering from primary malignant fibrous histio-cytoma was 22 2 % and the ten-year survival rate was 11 1 %

Of the nine patients suffering from primary malignant fibrous histio-cytoma, two lived for more than five years Both were treated by means of radical ablative surgery

5 11 2 6 3 NUD sarcoma

For NUD sarcoma both the five-year and ten-year survival rates were 11 1 %

5 11 2 6 4 Radiation sarcoma

The average period of survival for the two patients in the study was 0 3 years

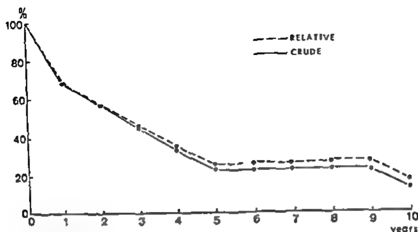

Figure 19 Survival curves for those suffering from primary malignant fibrous histiocytoma, 9 patients (relative and crude survival)

5 11 2 6 5 Fibrolipo myxoma malignum

The one patient in this study who had fibrolipo-myxoma malignum has lived, without symptoms, for eight years

5 11.2 6 6 Chondro-myxoma malignum

The only patient in this study who had chondro-myxoma malignum lived for 1 5 years after evacuation of a tumour in the trocanter of the femur

5 11 2 6 7 Fibro-myxoma malignum

The only patient in this study who had a fibro-myxoma malignum in the skull lived for 7 4 years after local exturpation and post-operative radiation treatment

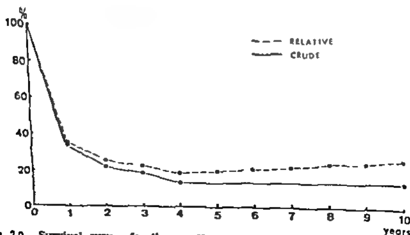

Figure 20 Survival curves for those suffering from NUD sarcoma, 18 patients (relative and crude survival)

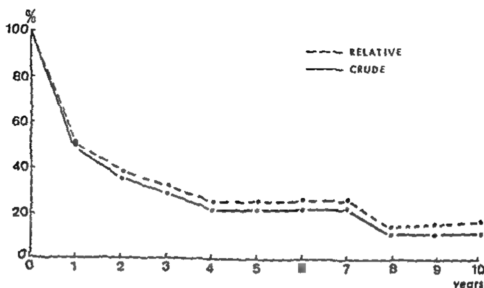

Figure 18 Survival curves for those suffering from fibro-sarcoma, 14 patients (relativ and crude survival)

5 11 2 5 2 Haemangio-pericytoma-sarcoma

Neither of the two patients suffering from haemangio-pericytoma-sarcoma lived as much as five years

5 11 2 5 3 Discussion

The prognosis for angio-sarcoma and haemangio-pericytoma-sarcoma cannot be established with any certainty on account of the rarity of these tumours The treatment recommended follows the same principles as that for osteo-sarcoma (Dahlin 1972) In the light of the individual cases in the present study it may be said that the tumours are rather malignant Prognosis is very poor

5 11 2 6 Other connective tissue tumours

5 11 2 6 1 Fibro-sarcoma

The 5-year survival rate for patients suffering from fibro-sarcoma was 21 5 % and the ten-year survival rate was 10 8 %

All the fibro-sarcoma patients who lived for more than five years were treated b means of radical surgery and radiation One tumour located in the mandibula wa treated by means of local evacuation anc radiation

5 11 2 6 2 Primary malignant fibrous histio-cytoma

The five-year survival rate for patients suffering from primary malignant fibrous histio-cytoma was 22 2 % and the ten-year survival rate was 11 1 %

Of the nine patients suffering from primary malignant fibrous histio-cytoma two lived for more than five years Both were treated by means of radical ablative surgery

5 11 2 6 3 NUD sarcoma

For NUD sarcoma both the five-year and ten-year survival rates were 11 1 %

5 11 2 6 4 Radiation sarcoma

The average period of survival for the two patients in the study was 0 3 years

6 GENERAL DISCUSSION

Between 1962 and 1968 a total of 985 new primary malignant bone tumours were recorded in the Finnish Cancer Registry The clinical follow-up comprised 869 patients (88 2 %), there were 316 cases of sarcoma and 553 cases of myeloma In Finland hospitals and departments of pathology are obliged to inform the authorities if they treat or diagnose malignant tumours and therefore the figures supplied by the Finnish Cancer Registry may be considered representative of the whole country

The age and sex distribution of the 869 patients with primary malignant bone tumour included in the clinical study corresponds to that in earlier reports (Dahlin 1972) There were no examples of the very rarest tumours in the present series Primary malignant fibrous histio-cytoma was diagnosed in Finland for the first time in this study and there were nine cases The basis for the histo-pathological classification was the schema published by the World Health Organization (Schajowicz et al 1972) supplemented by some additional categories for Finnish conditions (Sorvari 1976)

In bone sarcomas symptoms lasted 4 6 months and in myelomas 6 6 months. There were three cases where the correct diagnosis was not made and the patient received inadequate treatment In many cases the diagnosis was delayed after the primary lesion was detected

A correct radiological diagnosis was made, using ordinary radiographs, in 91 4 % of cases This corresponds approximately to results reported elsewhere (Lodwick 1967, Ranke 1968)

Angiography was usually helful for determining the extent of the tumour outside the bone involved Angiography may also be helpful for differentiating chondrosarcoma from benign osteo-chondroma, but in general it does not help when trying to distinguish between benign and malignant bone lesions (Yaghmai 1979) It is valuable in preoperative planning, particularly in the case of malignant tumours of the pelvis

Scintigraphy is an important method for revealing primary malignant bone tumours Because the series studied consists of cases in the nineteen-sixties, scintigraphy was used in only 26 cases No conclusions concerning its value can therefore be drawn It does, however, seem to be of great value for detecting local bone marrow and distant metastases It is also useful in planning radiographical examinations and in post-operative follow-up

A frozen section taken during surgery may sometimes be helpful, but generally the diagnosis should be made before surgery is embarked upon, radiologically and

5 11 2 6 8 Discussion

25 % of fibro-sarcomas are of the secondary type (Dahlin 1972), in the present study there was one fibro-sarcoma which stemmed from Paget's disease The survival rates published here correspond well with those reported elsewhere (Eyre-Brook et al 1969, Dahlin 1972) All the three patients who lived for more than five years were treated surgically and with radiation The treatment for fibro-sarcoma is the same as that for osteo-sarcoma

It is only a few years ago that primary malignant fibrous histio-cytoma was discovered and there is no information about prognosis In the present study it was found to be very malignant and prognosis was worse than for osteo-sarcoma The average period of survival was 1 8 years and the results of treatment were similar to those reported elsewhere (Spanjer et al 1975, Slootweg et al 1975, Webber et al 1977)

In the present study, NUD sarcoma was considered as a separate disease, because the most precise diagnosis possible in further histo-pathological study was that it was a primary bone tumour of the sarcoma type Prognosis was worse than for osteo-sarcoma and treatment must be as radical as for osteo-sarcoma

Radiation sarcoma, fibrolipo-myxoma malignum, chondro-myxoma malignum and fibro-myxoma malignum are all rare tumours and there is no precise information about prognosis or treatment Surgical treatment similar to that for osteo-sarcoma is necessary

5 11 2 7 Other tumours

5 11 2 7 1 Chordoma

There were five patients with chordoma in the present study One had a tumour in the spine and lived for 0 6 years and another had a tumour in the skull and lived for 1 3 years Three patients had a tumour in the sacrum, two of these were removed surgically and both the patients in question lived for 8 9 years The third, who only received basic treatment lived for 0 4 years

5 11 2 7 2 Neuro-sarcoma

Only one patient in the present study had neuro-sarcoma The tumour was located in the 4th lumbar vertebra After extirpation of the tumour and post-operative radiation treatment, this patient lived for 0 2 years

5 11 2 7 3 Discussion

Because of the anatomical location of the tumour, it is seldom possible with chordoma to undertake radical surgery However, the tumour grows slowly and thus palliative surgery often gives satisfactory results A similar picture is given by Greenwald (1957) and Dahlin (1972) In the present study, there was no case in which radical surgery was possible

Neuro-sarcoma is an extremely rare tumour and there are no reports about treatment or prognosis In the light of individual cases it has been considered that treatment should follow the same lines as that for osteo-sarcoma (Guthert 1972)

6 GENERAL DISCUSSION

Between 1962 and 1968 a total of 985 new primary malignant bone tumours were recorded in the Finnish Cancer Registry The clinical follow-up comprised 869 patients (88 2 %), there were 316 cases of sarcoma and 553 cases of myeloma. In Finland, hospitals and departments of pathology are obliged to inform the authorities if they treat or diagnose malignant tumours and therefore the figures supplied by the Finnish Cancer Registry may be considered representative of the whole country

The age and sex distribution of the 869 patients with primary malignant bone tumour included in the clinical study corresponds to that in earlier reports (Dahlin 1972) There were no examples of the very rarest tumours in the present series Primary malignant fibrous histio-cytoma was diagnosed in Finland for the first time in this study and there were nine cases The basis for the histo-pathological classification was the schema published by the World Health Organization (Schajowicz et al 1972) supplemented by some additional categories for Finnish conditions (Sorvari 1976)

In bone sarcomas symptoms lasted 4 6 months and in myelomas 6 6 months There were three cases where the correct diagnosis was not made and the patient received inadequate treatment In many cases the diagnosis was delayed after the primary lesion was detected

A correct radiological diagnosis was made, using ordinary radiographs, in 91 4 % of cases This corresponds approximately to results reported elsewhere (Lodwick 1967, Ranke 1968)

Angiography was usually helful for determining the extent of the tumour outside the bone involved Angiography may also be helpful for differentiating chondrosarcoma from benign osteo-chondroma, but in general it does not help when trying to distinguish between benign and malignant bone lesions (Yaghmai 1979) It is valuable in preoperative planning, particularly in the case of malignant tumours of the pelvis

Scintigraphy is an important method for revealing primary malignant bone tumours Because the series studied consists of cases in the nineteen-sixties, scintigraphy was used in only [illegible] cases No conclusions concerning its value can therefore be drawn It does, however, seem to be of great value for detecting local bone marrow and distant metastases It is also useful in planning radiographical examinations and in post-operative follow-up

A frozen section taken during surgery may sometimes be helpful, but generally the diagnosis should be made before surgery is embarked upon, radiologically and

with the aid of histological examination of adequate biopsy specimens In the present series a frozen section was examined in 41 cases and malignancy was confirmed in 85 4 % of these cases

There were two cases in this series where the malignancy was certainly caused by earlier radiation treatment There was one case where Paget's disease had developed into osteo-sarcoma, this is very rare in Finland The effect of radiation in Paget's disease is well documented (Marie et al 1910, Cohen et al 1948, Esposito et al 1960, MacKenzie et al 1967) Because of the risk involved, radiation treatment is no longer used for treating benign bone lesions In the present study, there was no case in which trauma could ascertained as an etiological factor, although it is often mentioned in literature on the subject (Phemister 1948, Hellner 1966 Fisher 1971)

Laboratory studies for bone sarcomas are simple routine tests and in the present study the results of these tests corresponded to those reported elsewhere (O Hara 1968, Derian et al 1972) Laboratory diagnosis of myeloma has developed rapidly and it was possible to classify 95 2 % of myelomas into immunological sub-groups Laboratory tests are of especial significance in following the progress of primary malignant tumours

In recent years since the practice of extensive bone resections became widespread, ablative surgery has been less favoured as a means of treating bone tumours In the present study 64 osteo-sarcoma patients (52 0 %) were treated by means of ablative surgery Radical bone resection was performed in 10 cases Since the period when the patients in this study were undergoing treatment allograft bone transplants and bio-mechanical prostheses have been developed, which make possible even more extensive bone resections (Volkov 1970, Parrish 1972, Ottolenghi 1973, Koskinen 1978) Local resection or evacuation proved to be a poor method of treatment, because of recurrence of tumours Evacuation was performed on six patients, many of whom later had to undergo amputation on account of recurrence This experience was similar to that reported by Koskinen (1978)

With the development of surgical and cytostat treatment, the importance of radiation for treating solid bone tumours has diminished in recent years (Koskinen 1976) However, even for osteogenic and chondrogenic tumours which cannot be radically removed, radiation treatment increases the survival time and it is justified as palliative treatment especially among older patients (Nordman 1979) In our study 99 sarcoma patients were treated with radiation only and it was commonly used as a supplement to surgery

Treatment with cytostatic agents has developed rapidly since the introduction of combined treatment Most patients in this study were given cytostat treatment which consisted of a small dose of a single drug 62 7 per cent of myeloma patients received cytostat treatment in some form

Immunological treatment and interferon are still at the experimental stage (Koskinen 1975 Tallberg 1976, Salenius 1977, Cantell 1978)

The therapy for primary bone sarcomas and multiple myelomas is very different Bone-forming tumours have long been treated by means of ablative surgery when this is anatomically possible The value of ablative surgery is reflected in the higher survival rates for patients with peripheral osteo-sarcomas Thus the five-year survival rate where there were tumours in the tibia was 45 0 % and where

there were tumours in the femur, 27 5 %. The five-year survival rate with humeral osteo sarcomas was only 7 7 %, which is lower than that reported by Dahlin (1972) Because this group consisted of five cases only and because the therapy was probably not quite adequate in all of these cases the difference is not significant

The five-year survival rate does not give a dependable picture of parosteal osteosarcoma because of the slow progression of the tumours and late development of metastases (Wolfel et al 1969) There were only four parosteal osteo-sarcomas in the present series and it is thus impossible to draw any conclusion

The prognosis for patients with cartilage-forming tumours is considered better that for those with osteo-sarcomas In the present series the five-year survival rate for primary chondro-sarcoma was 35 8 % and the ten-year survival rate was 27 3 %. Henderson and Dahlin (1963) reported a survival rate of 69 2 % in cases treated with adequate surgery No useful conclusions can be drawn from comparing these results with those of the present study because our patients received different, and sometimes also inadequate treatment

The prognosis for malignant giant-cell tumours is good when the primary treatment is radical (Dahlin 1972) Both the five-year and ten-year survival rates were treated by means of radical surgery and 64 0 %. In the present study eight patients were treated by means of radical surgery and seven by means of local surgery All these patients lived for more than five years The patients who underwent local surgery were all given radiation treatment

Bone-marrow tumours are usually very malignant primary bone tumours Theoretically massive combined treatment with cytostatic agents is especially indicated in order to destroy micro-metastases Particularly in the case of Ewing's sarcoma the results after a short follow-up have shown improvement The results of radical ablative surgery are not good In the present study, the prognosis for reticulum-cell sarcoma was worse than that reported in literature generally The five-year survival rate was 21 5 %, only three patients treated with radiation lived for five years, although it is generally considered that radiation gives good results in the treatment of reticulum-cell sarcoma (Coley et al 1950, Shoji et al 1971, Miller et al 1971) The prognosis for lympho-sarcoma was even worse, not a single patient surviving for as much as two years This is not as good as results reported elsewhere (Mincey et al 1974)

According to most investigators the best way of treating solitary myeloma is with a combination of surgery and radiation (Dahlin 1972) In individual cases, a period of survival as long as 30 years has been reported (Pancovich et al 1972) In the present study, the five-year survival rate was 50 0 % and the ten-year survival rate 25 0 %. It is known that as the years pass the disease develops into multiple myeloma and for that reason prognosis becomes worse as the follow-up time increases

The prognosis for patients suffering from multiple myeloma is known to be poor, few patients surviving more than five years (Copeland 1967, Baldwin et al 1967) In the present study the five-year survival rate was 4 8 %. There was no statistically significant difference in these rates when the treatment was a combination of different cytostatic agents and cortisone Of the patients who received only basic treatment, not one lived for five

years The immunological category to which the tumour belonged had no effect on the prognosis The average period of survival for patients in the present study was as follows IgA myeloma 0 8 years, IgG myeloma 1 1 years, IgM myeloma 0 9 years and NUD myeloma 0 7 years A comparison of the results reveals that after combined cytostat and radiation treatment the period of survival was 1 6 years, whereas a combination of radiation and cortisone when dealing with the IgG type of myeloma gave a survival period of 1 9 years However, on account of the small number of patients involved, these figures are not significant statistically

The five-year survival rate for patients suffering from extra-medullary plasmacytoma was 60 0 % and the ten year survival rate was 30 0 % These figures are in accord with what has been stated elsewhere about the development of late metastases (Gosepath et al 1969)

On the basis of individual cases reported in literature on the subject the treatment of and prognosis for primary malignant vascular tumours is the same as for osteo-sarcoma (Dahlin 1972)

In the case of other connective-tissue tumours it is typical that there is osteolytic damage, pathological fracture and the development of rather early metastases all of which mean a poor prognosis The five-year survival rate for fibro-sarcoma was 21 5 % which is about the same as that reported in other studies (Gilmer et al 1958 Eyre-Brook et al 1969 Dahlin et al 1969) In the present study those fibro-sarcoma patients who lived for more than five years had been treated surgically and had also had radiation treatment Because of the similar prognosis, the principles of treatment for osteo-sarcoma are completely applicable to fibro-sarcoma (Dahlin 1972) On account of its rarity and the small numbers involved, there is very little information about the prognosis and treatment for primary malignant fibrous histio-cytoma In the light of the present study it may be said that it is at least as malignant a tumour as osteo-sarcoma, develops metastases just as early and requires similar principles of treatment (Spanier et al 1975, Slootweg et al 1975) The cases reported here are the first primary malignant fibrous histio-cytomas to be diagnosed in Finland Because the prognosis is so bad, the NUD-sarcoma cases show convincingly that if it is not possible to achieve a clear histo-pathological diagnosis of malignancy, the tumour should be treated in the same way as osteo-sarcoma Radiation-sarcoma, fibrolipo-myxoma malignum, chondro-myxoma malignum and fibro-myxoma malignum must also be treated in the same way as osteo-sarcoma

Of those in the final group, »other tumours» chordoma is a tumour that grows slowly and can often only be treated palliatively Of the five chordoma patients in this study it was possible to treat only two by means of radical surgery For these the period of survival was ■9 years whereas the longest period for those who were not operated on radically was 1 3 years Treatment and prognosis for neuro-sarcoma are not well known The general principle of treatment is the same as for osteo-sarcoma (Gilbert 1972)

7 SUMMARY AND CONCLUSIONS

Between the years 1962 and 1968, 985 new cases of primary malignant bone tumour were reported by the Finnish Cancer Registry. Because hospitals and departments of pathology are obliged to report all new cases to the central authority these figures may be considered representative for the country as a whole. Incidence was 3.16 primary malignant bone tumours per 10^5 inhabitants annually. Primary malignant bone tumours accounted for 1.25 % of all malignant tumours. These figures are comparable to those reported elsewhere (Swedish Cancer Registry 1960, The Cancer Registry of Norway 1964, Bristol Bone Tumour Registry 1971, Ott et al 1977).

The final study comprised 869 patients suffering from primary malignant bone tumour. Age and sex distribution was similar to that in earlier studies.

Pain at the site of the tumour was the first symptom in 88.6 % of sarcoma patients and 92.4 % of myeloma patients. In the case of three patients correct treatment was significantly delayed because of a wrong diagnosis.

Plain radiography is the most important form of X-ray examination for primary malignant bone tumour. Angiography gives additional information that can be used in planning treatment. As it develops X-ray examination aided by computer will be useful. Providing as it does a reasonably sure pre-operative diagnosis, this will facilitate the making of decisions about the method of treatment to be adopted.

Diagnosis of primary malignant bone tumour should be based on a histological examination. In the present series, it was shown that study of frozen sections led in 85.4 % of cases to a diagnosis of certain malignancy and was thus valuable for making decisions about treatment.

Tumours were classified as 21 different histological types. There were 553 cases of myeloma (63.6 %), 123 cases of osteo-sarcoma (14.2 %) and 68 cases of chondro-sarcoma (7.7 %). These were the most common types.

For osteo-sarcoma radical ablative surgery was carried out on 64 patients, 32 of whom also had radiation treatment. Radical resection was performed on 10 patients, eight of whom received radiation treatment. Local resection was the treatment for six patients, all of whom were also treated with radiation. Evacuation was the treatment for six patients, five of these also being given radiation treatment. Radiation treatment was given to 26 patients, four of whom were also treated with cytostatic agents. There were eight patients who received no specific treatment, either because of their poor general condition or because they refused.

For chondro-sarcoma the number of pa-

years The immunological category to which the tumour belonged had no effect on the prognosis The average period of survival for patients in the present study was as follows IgA myeloma 0 8 years, IgG myeloma 1 1 years, IgM myeloma 0 9 years and NUD myeloma 0 7 years A comparison of the results reveals that after combined cytostat and radiation treatment the period of survival was 1 6 years, whereas a combination of radiation and cortisone when dealing with the IgG type of myeloma gave a survival period of 1 9 years However, on account of the small number of patients involved, these figures are not significant statistically

The five-year survival rate for patients suffering from extra-medullary plasmacytoma was 60 0 % and the ten year survival rate was 30 0 % These figures are in accord with what has been stated elsewhere about the development of late metastases (Gosepath et al 1969)

On the basis of individual cases reported in literature on the subject the treatment of and prognosis for primary malignant vascular tumours is the same as for osteosarcoma (Dahlin 1972)

In the case of other connective-tissue tumours it is typical that there is osteolytic damage, pathological fracture and the development of rather early metastases, all of which mean a poor prognosis The five-year survival rate for fibro-sarcoma was 21 5 %, which is about the same as that reported in other studies (Gilmer et al 1958, Eyre-Brook et al 1969 Dahlin et al 1969) In the present study those fibro-sarcoma patients who lived for more than five years had been treated surgically and had also had radiation treatment Because of the similar prognosis, the principles of treatment for osteo-sarcoma are completely applicable to fibro-sarcoma (Dahlin 1972) On account of its rarity and the small numbers involved, there is very little information about the prognosis and treatment for primary malignant fibrous histio-cytoma In the light of the present study it may be said that it is at least as malignant a tumour as osteo-sarcoma, develops metastases just as early and requires similar principles of treatment (Spanier et al 1975, Slootweg et al 1975) The cases reported here are the first primary malignant fibrous histio-cytomas to be diagnosed in Finland Because the prognosis is so bad, the NUD-sarcoma cases show convincingly that if it is not possible to achieve a clear histo-pathological diagnosis of malignancy, the tumour should be treated in the same way as osteo-sarcoma Radiation-sarcoma, fibrolipo-myxoma malignum, chondro-myxoma malignum and fibro-myxoma malignum must also be treated in the same way as osteo-sarcoma

Of those in the final group »other tumours» chordoma is a tumour that grows slowly and can often only be treated palliatively Of the five chordoma patients in this study it was possible to treat only two by means of radical surgery For these the period of survival was 8 9 years whereas the longest period for those who were not operated on radically was 1 3 years Treatment and prognosis for neuro-sarcoma are not well known The general principle of treatment is the same as for osteo-sarcoma (Gilbert 1972)

7 SUMMARY AND CONCLUSIONS

Between the years 1962 and 1968, 985 new cases of primary malignant bone tumour were reported by the Finnish Cancer Registry Because hospitals and departments of pathology are obliged to report all new cases to the central authority these figures may be considered representative for the country as a whole Incidence was 3 16 primary malignant bone tumours per 10^5 inhabitants annually Primary malignant bone tumours accounted for 1 25 % of all malignant tumours These figures are comparable to those reported elsewhere (Swedish Cancer Registry 1960, The Cancer Registry of Norway 1964 Bristol Bone Tumour Registry 1971, Ott et al 1977)

The final study comprised 869 patients suffering from primary malignant bone tumour Age and sex distribution was similar to that in earlier studies

Pain at the site of the tumour was the first symptom in 88 6 % of sarcoma patients and 92 4 % of myeloma patients In the case of three patients correct treatment was significantly delayed because of a wrong diagnosis

Plain radiography is the most important form of X-ray examination for primary malignant bone tumour Angiography gives additional information that can be used in planning treatment As it develops X-ray examination aided by compute- will be useful Providing as it does a reasonably sure pre-operative diagnosis, this will facilitate the making of decisions about the method of treatment to be adopted

Diagnosis of primary malignant bone tumour should be based on a histological examination In the present series, it was shown that study of frozen sections led in [illegible]4 % of cases to a diagnosis of certain malignancy and was thus valuable for making decisions about treatment

Tumours were classified as 21 different histological types There were 553 cases of myeloma (63 6 %), 123 cases of osteo-sarcoma (14 2 %) and 68 cases of chondro-sarcoma (7 7 %) These were the most common types

For osteo-sarcoma, radical ablative surgery was carried out on 64 patients, 32 of whom also had radiation treatment Radical resection was performed on 10 patients, eight of whom received radiation treatment Local resection was the treatment for six patients, all of whom were also treated with radiation Evacuation was the treatment for six patients, five of these also being given radiation treatment Radiation treatment was given to 26 patients, four of whom were also treated with cytostatic agents There were eight patients who received no specific treatment, either because of their poor general condition or because they refused

For chondro-sarcoma the number of pa-

years The immunological category to which the tumour belonged had no effect on the prognosis The average period of survival for patients in the present study was as follows IgA myeloma 0 8 years, IgG myeloma 1 1 years, IgM myeloma 0 9 years and NUD myeloma 0 7 years A comparison of the results reveals that after combined cytostat and radiation treatment the period of survival was 1 6 years, whereas a combination of radiation and cortisone when dealing with the IgG type of myeloma gave a survival period of 1 9 years However, on account of the small number of patients involved, these figures are not significant statistically

The five-year survival rate for patients suffering from extra-medullary plasmacytoma was 60 0 % and the ten year survival rate was 30 0 % These figures are in accord with what has been stated elsewhere about the development of late metastases (Gosepath et al 1969)

On the basis of individual cases reported in literature on the subject the treatment of and prognosis for primary malignant vascular tumours is the same as for osteo-sarcoma (Dahlin 1972)

In the case of other connective-tissue tumours it is typical that there is osteolytic damage, pathological fracture and the development of rather early metastases all of which mean a poor prognosis The five-year survival rate for fibro-sarcoma was 21 5 %, which is about the same as that reported in other studies (Gilmer et al 1958, Eyre-Brook et al 1969 Dahlin et al 1969) In the present study those fibro-sarcoma patients who lived for more than five years had been treated surgically and had also had radiation treatment Because of the similar prognosis, the principles of treatment for osteo-sarcoma are completely applicable to fibro-sarcoma (Dahlin 1972) On account of its rarity and the small numbers involved, there is very little information about the prognosis and treatment for primary malignant fibrous histio-cytoma In the light of the present study it may be said that it is at least as malignant a tumour as osteo-sarcoma, develops metastases just as early and requires similar principles of treatment (Spanier et al 1975, Slootweg et al 1975) The cases reported here are the first primary malignant fibrous histio-cytomas to be diagnosed in Finland Because the prognosis is so bad, the NUD-sarcoma cases show convincingly that if it is not possible to achieve a clear histo-pathological diagnosis of malignancy, the tumour should be treated in the same way as osteo-sarcoma Radiation-sarcoma, fibrolipo-myxoma malignum, chondro-myxoma malignum and fibro-myxoma malignum must also be treated in the same way as osteo-sarcoma

Of those in the final group, »other tumours» chordoma is a tumour that grows slowly and can often only be treated palliatively Of the five chordoma patients in this study it was possible to treat only two by means of radical surgery For these the period of survival was 8 9 years whereas the longest period for those who were not operated on radically was 1 3 years Treatment and prognosis for neuro-sarcoma are not well known The general principle of treatment is the same as for osteo-sarcoma (Gilbert 1972)

8 ACKNOWLEDGEMENTS

I began the present study when I was working at the surgical clinic of the University Hospital in Turku, under the supervision of Professor Sauli Viikari, whose support and expert advice I here acknowledge with deepest gratitude. I owe a particular debt also to Professor Erkki Saxen, director of the Finnish Cancer Registry who kindly made important records available to me. The further study of original histological material carried out by Dr Tapani Sorvari was indispensable and for that work as well as much wise counsel received in the course of numerous discussions with him I am profoundly grateful. Dr Sorvari's wide knowledge of the field has moreover enabled me to gain many valuable insights concerning bone pathology and the intricacies of clinical examination. In this context I wish to thank also Dr Timo Romppainen for his assistance with the study of the histological material. I am profoundly appreciative of the help accorded me by Professor Pekka Virtama: he generously included me in his bone tumour study group and I have benefited greatly from the wisdom of his advice in matters radiological. Professor Virtama's further contribution in analysing the X-rays used in this study, in checking the *first draft* of the radiological section of my work and in suggesting improvements to the text in the course of writing is hereby gratefully acknowledged. I wish likewise to convey my thanks to Dr Kalevi Katevuo for helping with the analysis of X-rays. I have been greatly helped, especially in the final stages of composition, by the sympathetic interest of Dr Par Slatis, head of the Division of Orthopaedic Surgery and Traumatology, Surgical Hospital, University Central Hospital, Helsinki, where I am at present working. The assistance I have received from Dr Allan Aho, Assistant Professor of Surgery in Turku, has been spread over many years: he has followed the vicissitudes of the study from the very beginning and he has been unstinting in his advice and encouragement. He has also served as one of the official examiners and I have benefited in numerous ways from his wide clinical experience in the field of bone tumours. My obligation to Dr Aho is thus considerable and I extend him my heartfelt thanks. I acknowledge, with respect, the contribution made to this study by Professor Erkki V. S. Koskinen. I have had the inestimable advantage of his friendship over many years and have been privileged to draw upon his wide experience in innumerable discussions. I remain especially indebted to him for what he has taught me about clinical investigations but I have also been able, under his guidance, to follow the progress of bone tumour patients undergoing treatment. Professor Koskinen was also an offi-

tients who underwent radical ablative surgery was 22, seven of whom had radiation treatment Radical resection was performed on eight patients, only one of these receiving radiation treatment Nine patients had local resection, two of them also receiving radiation treatment Evacuation was the treatment for four patients In all, 22 patients received radiation treatment and of these, three also had cytostat treatment Three patients received no specific treatment

Metastases developed in more than 50 % of the sarcoma patients within six months Patients suffering from secondary chondro-sarcoma or malignant giant-cell tumours had fewer metastases It was unusual for metastases to develop later than 12 months after patients presented themselves for treatment

The five-year survival rate for osteo-sarcoma was 28 4 % and the ten-year survival rate was 24 8 % For primary chondro-sarcoma, the corresponding figures were 35 8 % and 27 3 %, for secondary chondro-sarcoma, 66 7 % and 58 8 % The five-year and ten-year survival rates for malignant giant-cell tumours were 64 0 % The corresponding figure for Ewing's sarcoma was 16 6 % For reticulum-cell sarcoma the five-year survival rate was 21 5 % and the ten-year survival rate was 12 9 % No patient suffering from lympho-sarcoma lived as long as two years

The average period of survival for patients with multiple myeloma was 0 9 years For those with the IgG type of myeloma the five-year survival rate was 6 4 % and ten-year survival rate was 4 3 % The corresponding figures for other types were worse

The prognosis for fibro-sarcoma was worse than that for osteo-sarcoma The five-year survival rate was 21 5 % and the ten-year survival rate was 10 8 % Malignant fibrous histio-cytoma of the bone is a very malignant tumour The five-year survival rate was 22 2 % and the ten-year survival rate was 11 1 % The prognosis for NUD sarcoma is very poor The five-year survival rate is 11 1 % and the ten-year survival rate is the same

In the light of the present study it may be asserted that because primary malignant bone tumours are rare and because the symptoms are rather slight, diagnosis may be delayed Diagnosis should be based on histological examination and active treatment must be begun at once The use of a combination of cytostatic agents has become an important method of treatment, particularly for bone-marrow tumours Malignant fibrous histio-cytoma of the bone, now diagnosed in Finland for the first time, is a very malignant tumour which must be treated according to the same principles as osteo-sarcoma If it is impossible to achieve an absolutely certain diagnosis for a primary bone tumour, but malignancy has been confirmed, the procedure for treatment should be as for osteo-sarcoma

Generally speaking these has been a somewhat pessimistic view of the results of treatment in cases of primary malignant bone tumour The present study shows, however that prompt diagnosis and adequate treatment may considerably improve the prognosis and help patients, many of whom are younger than in other malignant diseases If treatment were concentrated in important centres it seems seasnably certain that results would be even better

cial examiner for the thesis and his advice has helped me in many ways

Among the many others who have rendered assistance I cannot omit to thank the following Mr Kari Helander, for familiarizing me with the statistical treatment of the material and looking after the automatic data processing, Mr & Mrs Antony Landon for translating the Finnish manuscript, Mrs Kirsti Lundstedt for drawing the pictures, Miss Pirjo Rasivaara and Mrs Terttu Kaisti for helping me to assemble material in the early stages, the heads of various hospitals and departments for supplying material, the staff of the Turku University medical library for their courtesy and co-operation

Finally a word of praise for my long suffering family Without the patience and fortitude shown by my wife and children during the long years of waiting it is doubtful whether this book would ever have been completed They have been to me a constant source of inspiration

I am obliged to the Finnish Cancer Society for financial assistance

INTRODUCTION

The pathogenesis of osteoarthritis [redacted] still not known In general the disease is regarded as [redacted] result of "degeneration", [redacted] wear and tear phenomenon as well as a disorder of advanced age

Over the years innumerable studies have been concerned with attempts [redacted] elucidate this disorder Most investigators have been engaged in the study of articular cartilage, and alterations in this tissue usually are considered the primary stage of osteoarthritis Others have entertained the idea that basically osteoarthritis is a vascular disease and that the initial changes are to be found in the subchondral bone However, the cause of these changes is still obscure Although general factors may contribute to certain forms of osteoarthritis, it is generally agreed that local factors are of more importance These may vary from joint to joint

The present paper deals with the pathomechanism of "primary" osteoarthritis of the hip joint It has been our intention to analyse the results of a series of investigations on changes in the synovial membrane, the synovial fluid, articular cartilage and the sub- and juxtachondral bone and bone marrow Our choice of methods depended on the resources of our laboratories, and the subjects of investigation upon a working hypothesis developed during the years 1970-1975 (Fig 1) Thus, this work is not intended as a systematic treatise on the pathogenesis of osteoarthritis Instead, it is first and foremost a synthesis of our findings, a search for internal correlation and an attempt to determine which of the many gaps in our knowledge are of most importance for further studies

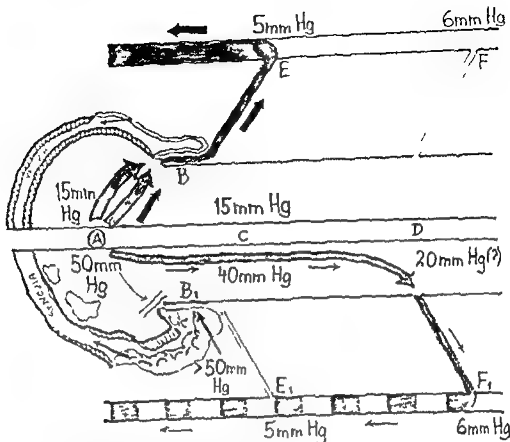

Fig 1 The data known from intraosseous pressure measurements and phlebography in 1975, and the basis for the studies represented in this paper

THE SYNOVIAL MEMBRANE

The histopathological features of osteoarthritic synovium have been considered non-specific (Roy 1967) and controversy about the *role of the synovial* membrane has persisted Though many are of the opinion that changes in the synovium are secondary to cartilage destruction and result from displacement of joint detritus into the synovium (Lloyd Roberts 1953), it is a clinical experience that synovitis is a very early and consistent feature also *in primary* osteoarthritis

In contrast to rheumatoid synovium the changes in the synovial membrane of osteoarthritic joints described in the literature are not very detailed Proliferation of lining cells, hypertrophy of villi and absence of, or only slight, inflammatory changes have been mentioned (Wilkinson & Jones 1963, Roy 1967, Huth et al 1973) and vascular changes *of the same* pattern as observed in rheumatoid arthritis were described by Goldie (1970)

INTRODUCTION

The pathogenesis of osteoarthritis is still not known In general the disease is regarded as a result of "degeneration", a wear and tear phenomenon as well as a disorder of advanced age

Over the years innumerable studies have been concerned with attempts to elucidate this disorder Most investigators have been engaged in the study of articular cartilage, and alterations in this tissue usually are considered the primary stage of osteoarthritis Others have entertained the idea that basically osteoarthritis is a vascular disease and that the initial changes are to be found in the subchondral bone However, the cause of these changes is still obscure Although general factors may contribute to certain forms of osteoarthritis, it is generally agreed that local factors are of more importance These may vary from joint to joint

THE SYNOVIAL MEMBRANE

The histopathological features of osteoarthritic synovium have been considered non specific (Roy 1967) and controversy about the role of the synovial membrane has persisted. Though many are of the opinion that changes in the synovium are secondary to cartilage destruction and result from displacement of joint detritus into the synovium (Lloyd Roberts 1953), it is a clinical experience that synovitis is a very early and consistent feature also in primary osteoarthritis.

In contrast to rheumatoid synovium the changes in the synovial membrane of osteoarthritic joints described in the literature are not very detailed. Proliferation of lining cells, hypertrophy of villi and absence of or only slight inflammatory changes have been mentioned (Wilkinson & Jones 1963, Roy 1967, Huth et al 1973) and vascular changes of the same pattern as observed in rheumatoid arthritis were described by Goldie (1970).

INTRODUCTION

The pathogenesis of osteoarthritis is still not known In general the disease is regarded as a result of "degeneration", a wear and tear phenomenon as well as a disorder of advanced age

Over the years innumerable studies have been concerned with attempts to elucidate this disorder Most investigators have been engaged in the study of articular cartilage, and alterations in this tissue usually are considered the primary stage of osteoarthritis Others have entertained the idea that basically osteoarthritis is a vascular disease and that the initial changes are to be found in the subchondral bone However, the cause of these changes is still obscure Although general factors may contribute to certain forms of osteoarthritis, it is generally agreed that local factors are of more importance These may vary from joint to joint

The present paper deals with the pathomechanism of "primary" osteoarthritis of the hip joint It has been our intention to analyse the results of a series of investigations on changes in the synovial membrane, the synovial fluid, articular cartilage and the sub- and juxtachondral bone and bone marrow Our choice of methods depended on the resources of our laboratories, and the subjects of investigation upon a working hypothesis developed during the years 1970 1975 (Fig 1) Thus, this work is not intended as a systematic treatise on the pathogenesis of osteoarthritis Instead, it is first and foremost a synthesis of our findings, a search for internal correlation and an attempt to determine which of the many gaps in our knowledge are of most importance for further studies

Fig 3 A *Synovial membrane from a man aged 63 with coxarthrosis Marked venous stasis Haematoxylin/eosin magnification x 25*
B *Same as A Note interstitial oedema Magnification x 100*
C *Synovial membrane from a woman aged 64 with fracture of the femoral neck Haematoxylin/eosin magnification x 25*

Compared with the control group the biopsies from both osteoarthritic and rheumatoid arthritic hip joints showed characteristic vascular changes The venules and capillaries were dilated and packed with erythrocytes (Fig 3 A B and C) hypertrophy of the arterioles was often present and an increased permeability of the capillary wall was suggested by the presence of interstitial oedema free erythrocytes and haemosiderine deposits in the interstitial tissue (proliferative type) In almost half the cases of osteoarthritis there was an increased amount of fibrosis (fibrous type)

Electron microscopy Electron microscopy confirmed the changes seen by light microscopy Free erythrocytes were often seen in the interstitial tissue or penetrating the capillary wall which was intact and of normal appearance This is in accordance with the observations by Dryll et al (1977) who have shown an increased transcapillary migration of circulating blood cells but a normal structure of the capillary wall

Histochemical investigations

Compared with rheumatoid arthritis only slightly increased levels of acid and alkaline hydrolase activity have been demonstrated by biochemical methods (Kar et al 1976) In order to investigate whether this increased activity is consistent with the morphological changes of the synovial membrane seen in our histological studies a histochemical analysis of alkaline and acid phosphatase in osteoarthritic synovium from human hip joints was carried out (Reimann & Christensen 1979)

Frozen sections of synovial biopsies from 12 osteoarthritic hip joints were studied Biopsy samples from six patients with fracture of the femoral neck were used as control together with two biopsies from the knee joints of young patients with torn menisci The *enzymo-histochemical* analyses were performed using Burstone s (1959) method for demonstration of non-specific alkaline phosphatase

Recently a grading system of the histological criteria for inflammation has been proposed (Salvati et al 1977) and an increased enzyme level has been demonstrated biochemically (Kar et al 1976, Salvati et al 1977)

Own Investigations

Electron and light microscopic study of the synovial membrane

To explore the representative features in osteoarthritic synovium we performed an electron and light microscopic study of the synovial membrane from human hip joints The material consisted of biopsies from 24 osteoarthritic hip joints, and for comparison, biopsies from twelve patients with rheumatoid arthritis Biopsies from eight patients with fracture of the femoral neck were used as controls (Arnoldi et al in press 1979 c)

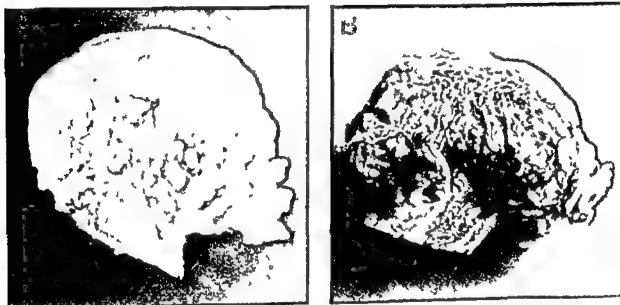

Fig 2 A Femoral head from a woman aged 71 with coxarthrosis and proliferative synovitis
B Femoral head from a man aged 71 with coxarthrosis and fibrous synovitis

Gross inspection of the synovial membrane in coxarthrosis Two relatively distinct types of 'synovitis' were observed in patients with coxarthrosis an early proliferative type and a late fibrous type The proliferative type was characterized by increase of synovial fluid in the joint and bulky volume of the synovium, the oedematous tissue often having the appearance of a juicy bunch of grapes (Fig 2 A) In the fibrous type most of these grapelike protuberances had disappeared and been replaced by stringy bands of fibrous scar tissue (Fig 2 B) In the fibrous type the hip joint usually contained very little fluid

Light microscopy The light microscopic examinations revealed that the osteoarthritic synovium as estimated by the grading system introduced by Salvati et al (1977) only showed slight to moderate degrees of inflammation in contrast to the rheumatoid synovium, which was characterized by pronounced focal as well as diffuse inflammation

oedematous fluid and to haemosiderine deposits in the interstitial tissue The subsequent development of fibrosis and scarry transformation of the synovial membrane is probably the long term reaction of mesenchymal tissue to these changes This conception is supported by the knowledge of a similar process which develops in the skin and subcutaneous tissues of the ankle region in patients with chronic venous insufficiency In these patients a purely mechanical disorder of the venous pump of the calf leads to an ambulatory hypertension in the veins and venules of the ankle region with impeded capillary flow (Arnoldi 1966) The early reaction is oedema and increased capillary permeability to proteins and erythrocytes (Zweifach 1940) Large deposits of haemosiderine in the interstitial tissue give rise to the well known brown discolouration in the lower leg that is so common in these patients Haemosiderine is a strong tissue irritant and causes an inflammatory reaction in the subcutis which undergoes a scarry transformation The previously swollen leg shrinks The scarry tissue is palpable as induration" The final stage of this "degenerative" process is the chronic venous leg ulcer (Haxthausen 1936, Arnoldi & Linderholm 1968, Arnoldi 1976)

Any process that results in an elevation of intraarticular pressure could probably initiate the changes observed in the osteoarthritic synovium Examination of pressures in the extraarticular veins of the hip region (Arnoldi et al 1979 a) indicates that elevation of intraarticular pressure by as little as 5 mmHg is sufficient to impede the flow through the synovial veins (see later) The process may begin as an inflammatory reaction caused e g by trauma or mechanical dysfunction of the joint with increased production of synovial fluid Due to the rigid character of the fibrous capsule any increase in volume is accompanied by an increased intraarticular pressure that in its turn will block the venous blood flow and add the effect of venous stasis to the inflammatory reaction (Arnoldi et al 1979 a) The subsequent effect of further increased capillary permeability could result in a self perpetuating process

THE SYNOVIAL FLUID

As synovial fluid is a dialysate of blood plasma to which hyaluronate – synthesized by synovial lining cells – is added, the changes in the synovial membrane in coxarthrosis described above should be reflected in the composition of the synovial fluid As shown by Lund-Olesen (1970) there seems to be a decreased oxygen tension in synovial fluid from osteoarthritic joints, but to a lesser degree than in rheumatoid synovia He also observed a significant correlation between PO_2 and pH and between PO_2 and PCO_2 It is known that the protein concentration in osteoarthritic synovia is slightly increased (Ropes & Bauer 1953), and that *there is an abnormal* protein pattern (Kushner & Sommerville 1971, Pruzanski et al 1973, Willumsen & Friis 1975) Further it has been shown that the passage of protein through the synovial vascular walls is affected by molecular size and by presence of inflammation (Kushner & Sommerville 1971)

Own investigations

Protein analysis

To elucidate the permeability of the osteoarthritic synovium to plasma proteins of varying molecular size we performed an analysis of the ratios of synovial fluid concentration to serum concentration (SF/S) for four non immunoglobulin proteins from osteoarthritic and normal hip joints We also

activity, and Barka & Anderson s (1963) method for demonstration of acid phosphatase activity For semiquantitative estimation of the enzyme activity the initial time was used, as described by Hopsy & Glenner (1965)

The enzyme levels were significantly increased in the osteoarthritic synovium compared with the controls The significance of increased alkaline phosphatase activity is not yet clear However, the alkaline phosphatase was found located in fibroblasts below the lining cells and in capillaries and precapillary arterioles Thus, the increased activity is presumably consistent with the increased vascularity and fibrosis found by histological examinations

Fig 4 A *Frozen section from osteoarthritic synovium The acid phosphatase reaction is seen in superficial lining cells (arrows) Magnification x 100*
B *Frozen section from control synovium The acid phosphatase reaction is seen in a few of the superficial lining cells Magnification x 100*

It is generally agreed that increased acid phosphatase activity is involved in the process leading to cartilage damage Other lysosomal enzymes presumably play a greater role, but acid phosphatase is a good marker enzyme for lysosomal enzymes As acid phosphatase was found located in the lining cells (Fig 4 A and B), probably mainly in the A type which is rich in lysosomes the proliferation of the lining cells – a general histological finding in various types of synovitis – is probably a contributory factor to the increased activity

The histochemical changes observed in the synovium thus seem to correlate with the histological findings

Discussion

In patients with coxarthrosis the histological examination of the synovium in proliferative synovitis shows a picture that is dominated by venous stasis and capillary dilation The few and scattered inflammatory cells could well be explained as a reaction to increased protein content in the

oedematous fluid and to haemosiderine deposits in the interstitial tissue The subsequent development of fibrosis and scarry transformation of the synovial membrane is probably the long term reaction of mesenchymal tissue to these changes This conception is supported by the knowledge of a similar process which develops in the skin and subcutaneous tissues of the ankle region in patients with chronic venous insufficiency In these patients a purely mechanical disorder of the venous pump of the calf leads to an ambulatory hypertension in the veins and venules of the ankle region with impeded capillary flow (Arnoldi 1966) The early reaction is oedema and increased capillary permeability to proteins and erythrocytes (Zweifach 1940) Large deposits of haemosiderine in the interstitial tissue give rise to the well known brown discolouration in the lower leg that is so common in these patients Haemosiderine is a strong tissue irritant and causes an inflammatory reaction in the subcutis which undergoes a scarry transformation The previously swollen leg shrinks The scarry tissue is palpable as "induration" The final stage of this "degenerative" process is the chronic venous leg ulcer (Haxthausen 1936, Arnoldi & Linderholm 1968, Arnoldi 1976)

Any process that results in an elevation of intraarticular pressure could probably initiate the changes observed in the osteoarthritic synovium Examination of pressures in the extraarticular veins of the hip region (Arnoldi et al 1979 a) indicates that elevation of intraarticular pressure by as little as 5-10 mmHg is sufficient to impede the flow through the synovial veins (see later) The process may begin as an inflammatory reaction caused e g by trauma or mechanical dysfunction of the joint with increased production of synovial fluid Due to the rigid character of the fibrous capsule any increase in volume is accompanied by an increased intraarticular pressure that in its turn will block the venous blood flow and add the effect of venous stasis to the inflammatory reaction (Arnoldi et al 1979 a) The subsequent effect of further increased capillary permeability could result in a self perpetuating process

THE SYNOVIAL FLUID

As synovial fluid is a dialysate of blood plasma to which hyaluronate – synthesized by synovial lining cells – is added, the changes in the synovial membrane in coxarthrosis described above should be reflected in the composition of the synovial fluid As shown by Lund-Olesen (1970) there seems to be a decreased oxygen tension in synovial fluid from osteoarthritic joints but to a lesser degree than in rheumatoid synovia He also observed a significant correlation between PO_2 and pH and between PO_2 and PCO_2 It is known that the protein concentration in osteoarthritic synovia is slightly increased (Ropes & Bauer 1953) and that there is an abnormal protein pattern (Kushner & Sommerville 1971, Pruzanski et al 1973, Willumsen & Friis 1975) Further it has been shown that the passage of protein through the synovial vascular walls is affected by molecular size and by presence of inflammation (Kushner & Sommerville 1971)

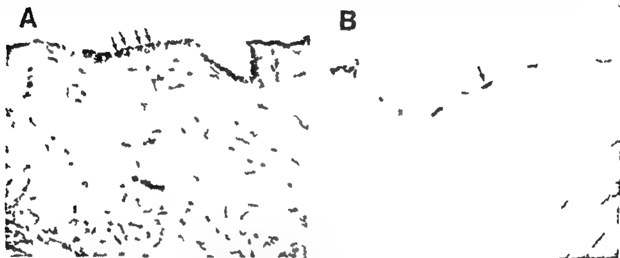
Own investigations

Protein analysis

To elucidate the permeability of the osteoarthritic synovium to plasma proteins of varying molecular size we performed an analysis of the ratios of synovial fluid concentration to serum concentration (SF/S) for four non immunoglobulin proteins from osteoarthritic and normal hip joints We also

activity and Barka & Anderson's (1963) method for demonstration of acid phosphatase activity. For semiquantitative estimation of the enzyme activity the initial time was used as described by Hopsy & Glenner (1965).

The enzyme levels were significantly increased in the osteoarthritic synovium compared with the controls. The significance of increased alkaline phosphatase acticity is not yet clear. However, the alkaline phosphatase was found located in fibroblasts below the lining cells and in capillaries and precapillary arterioles. Thus, the increased activity is presumably consistent with the increased vascularity and fibrosis found by histological examinations.



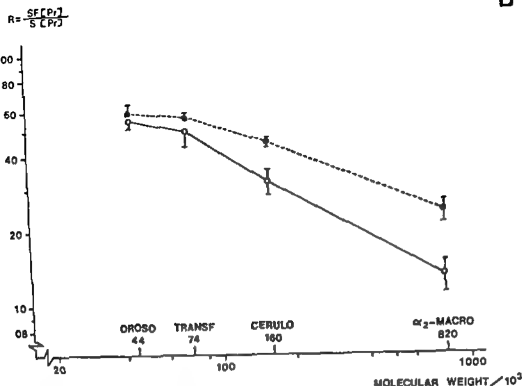


Fig. 4. A. *Frozen section from osteoarthritic synovium. The acid phosphatase reaction is seen in superficial lining cells (arrows). Magnification x 100.*
B. *Frozen section from control synovium. The acid phosphatase reaction is seen in a few of the superficial lining cells. Magnification x 100.*

It is generally agreed that increased acid phosphatase activity is involved in the process leading to cartilage damage. Other lysosomal enzymes presumably play a greater role, but acid phosphatase is a good marker enzyme for lysosomal enzymes. As acid phosphatase was found located in the lining cells (Fig. 4 A and B), probably mainly in the A type which is rich in lysosomes, the proliferation of the lining cells – a general histological finding in various types of synovitis – is probably a contributory factor to the increased activity.

The histochemical changes observed in the synovium thus seem to correlate with the histological findings.

Discussion

In patients with coxarthrosis the histological examination of the synovium in proliferative synovitis shows a picture that is dominated by venous stasis and capillary dilation. The few and scattered inflammatory cells could well be explained as a reaction to increased protein content in the

B *Intraindividual values from eight patients*

Our results showed that the variations in SF/S ratios from the normal hip joints were insignificant Furthermore, the analyses showed the same pattern in an intraindividual study as when all the samples from the osteoarthritic joints were compared with the normal samples (Fig 5 A and B)

The analyses showed a relationship between SF/S and molecular weight as described previously (Nettelbladt & Sundblad 1959, Kushner & Sommerville 1971, Pruzanski et al 1973, Willumsen & Friis 1975) The ratios were higher for osteoarthritic synovia than for normal, and the difference increased with increasing molecular weight and was highly significant for the largest molecules ($p<0.001$) An almost inverse linear relationship was observed between SF/S ratios of the proteins and their molecular weight (Fig 5 A and B) These findings indicate an increased capillary permeability in the synovial membrane

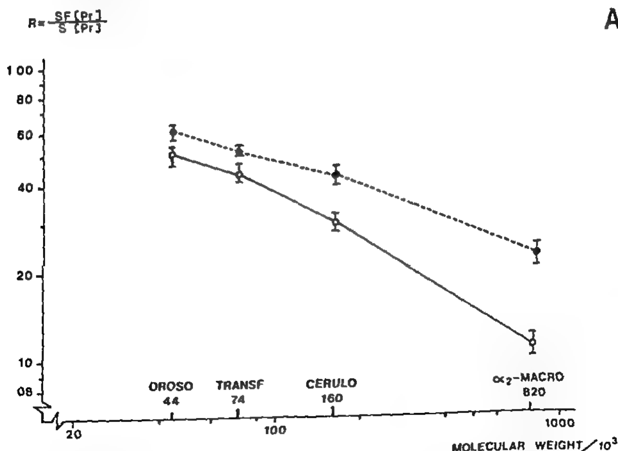
Relationship between protein ratios and inflammation in synovial fluid in different joint diseases has been described by Kushner & Sommerville (1971) They found that increasing degrees of inflammation corresponded to higher SF/S ratios with greatest increases in large molecules Patients with osteoarthritis showed least evidence of inflammation

In this series the degree of inflammation was estimated by histological examination of the synovial membrane It was impossible to correlate the degree of inflammation in the synovium with the protein ratios owing to the very slight degree of inflammation observed in the osteoarthritic synovium

investigated whether these changes were correlated to the histological features in the synovial membranes in patients with coxarthrosis (Reimann et al , in press 1979)

The synovial fluid was obtained at the time of replacement surgery from 46 patients with unilateral coxarthrosis Blood samples from a vein on the forearm were taken simultaneously Criteria for unilateral coxarthrosis were that the patients showed a radiologically normal contralateral hip without clinical symptoms and that there was no accentuation of the normal uptake pattern at osteoscintigraphy with ^{99m}Tc polyphosphate (Heerfordt et al 1976)

The simultaneously aspirated synovial fluids and sera were analysed with electro immunoassay as described by Laurell (1965) The proteins studied were orosomucoid, molecular weight 44,000, transferrin (74,000), ceruloplasmin (160,000) and α_2 macroglobulin (820,000) Recently, it has been shown that Stoke's radius, which is a function of molecular weight, volume and shape, is a more appropriate expression of protein size than molecular weight alone (Burnett et al 1975) However, the size of Stoke's radius for the four proteins investigated roughly correlates with the molecular weight (Burnett et al 1976, Renkin 1977) Further, local synthesis or destruction in the synovial membrane of these proteins has not been shown (Kushner & Sommerville 1971) The SF/S ratio thus reflects the synovial permeability for the single protein



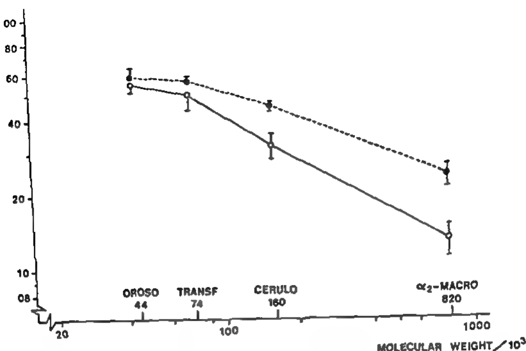


Fig 5 A Log/log plot of SF/S ratio and molecular weight from hip joints with osteoarthritis (black circles) and from normal hip joints (open circles) Ratio determined for the four non immunoglobulin proteins represent the mean∓ SD of 29 and 23 samples respectively

B *Intraindividual values from eight patients*

Our results showed that the variations in SF/S ratios from the normal hip joints were insignificant Furthermore, the analyses showed the same pattern in an intraindividual study as when all the samples from the osteoarthritic joints were compared with the normal samples (Fig 5 A and B)

The analyses showed a relationship between SF/S and molecular weight as described previously (Nettelbladt & Sundblad 1959, Kushner & Sommerville 1971, Pruzanski et al 1973, Willumsen & Friis 1975) The ratios were higher for osteoarthritic synovia than for normal, and the difference increased with increasing molecular weight and was highly significant for the largest molecules ($p<0\ 001$) An almost inverse linear relationship was observed between SF/S ratios of the proteins and their molecular weight (Fig 5 A and B) These findings indicate an increased capillary permeability in the synovial membrane

Relationship between protein ratios and inflammation in synovial fluid in different joint diseases has been described by Kushner & Sommerville (1971) They found that increasing degrees of inflammation corresponded to higher SF/S ratios with greatest increases in large molecules Patients with osteoarthritis showed least evidence of inflammation

In this series the degree of inflammation was estimated by histological examination of the synovial membrane It was impossible to correlate the degree of inflammation in the synovium with the protein ratios owing to the very slight degree of inflammation observed in the osteoarthritic synovium

As previously described, it is possible to distinguish between a proliferative and a fibrous type of synovitis in coxarthrosis By comparing the ratios of the four proteins in these two types it was found that patients with proliferative synovitis showed higher SF/S ratios than those with fibrous synovitis The difference was significant for α_2–macroglobulin ($p<0.01$) Thus the abnormal protein pattern in osteoarthritic synovia reflects an increased capillary permeability in the synovial membrane and it seems to correlate with the histological features

Discussion

Swelling and pain are regular features in all inflammatory joint disease, typified by rheumatoid arthritis It is also a common symptom after trauma or overloading, more easily noticed, e g in the knee than in the hip joint The patient with primary coxarthrosis is generally in his late fifties or sixties when he is seen by the orthopaedic surgeon However, a careful history will often reveal periods of intermittent pain in the hip region, combined with limping, during the years preceding the state of manifest osteoarthritis. During this period, when the X rays are normal, the patients are rarely seen by the orthopaedic surgeon, but by their family physician or a rheumatologist The treatment – if any – is conservative, mainly consisting of rest, occasionally combined with physical treatment of various kinds, and during the recent decade medication with one or several of the non steroid antiphlogistica This conservative regimen is often effective, but in some cases the symptoms return periodically until the diagnosis osteoarthritis becomes obvious This conservative treatment is essentially a treatment of synovitis

Thus, there are clinical indications that even primary coxarthrosis does not appear suddenly and without warning sometime after the fifty-fifth birthday The history is more likely to suggest that clinical osteoarthritis is the final stage of a fairly long lasting joint disorder Our clinical experience suggests that many attacks of synovitis disappear without doing permanent damage to the joint In certain cases the attack leads to manifest coxarthrosis within a short period of time but in most cases of primary coxarthrosis the synovitic episodes stretch over a number of years before the typical roentgen changes become visible

Inflammation, joint effusion and subsequent stasis result in a vascular derangement in the synovial membrane Increased capillary permeability is followed by a change in the protein pattern and the amount of protein in the synovia One of the functions of the synovial fluid is joint lubrication As shown by Reimann et al (1975) and Reimann (1976) boundary lubrication is reduced in rheumatoid arthritis and osteoarthritis It seems probable that this deterioration is due to the change in the protein pattern of the synovial fluid

The increased production of acid phosphatase and lysosomes known to be of importance for the degenerative changes of articular cartilage and the reduction of oxygen in the synovial fluid (Lund Olesen 1970) are of special importance as the synovia is the vehicle for supply of oxygen and nutrition to the cartilage Further, decreased oxygen tension is of significance for release of lysosomal enzymes (de Duve 1964)

The mechanical effect of synovitic joint effusion is discussed on p 21

VASCULAR CHANGES IN JUXTAARTICULAR BONE MARROW

The fact that degenerative changes usually are caused by a failure in the supply of oxygen and nutrition to the tissues involved focussed attention on the state of the arterial supply to the joint in many early studies on osteoarthritis As late as the middle of this century many authors were of the opinion that osteoarthritis of the hip was accompanied or preceded by a state of ischaemia of sub- and juxtachondral bone (Wollenberg 1909, Goldhaft et al 1930, Phemister 1940, Pridie 1952) This conception was challenged by Harrison et al (1953) By means of injection studies on cadavers they *found a hyperplasia of the intraosseous arteries in the femoral head and on the basis of this* observation they assumed that the arterial inflow to the femoral head was increased instead of reduced in coxarthrosis The same authors also found signs of venous stasis in the bone marrow

In the years following this study investigations by means of intraosseous phlebography provided evidence of disturbed venous outflow from the femoral head and neck in patients with coxarthrosis and from the distal part of the femur in patients with gonarthrosis (Ménel et al 1955, Hulth 1959, Helal 1962, Wardle 1964 Phillips 1966) and increased intramedullary pressure in juxtachondral bone marrow (Arlet et al 1968)

Own Investigations

Intraosseous phlebography and measurements of intraosseous pressure

Coxarthrosis In a series of 15 patients with unilateral painful primary osteoarthritis of the hip joint, Arnoldi et al (1972 a) measured the pressure in the bone marrow of both femoral necks and the femoral vein These examinations were followed by bilateral serial intraosseous phlebography of the proximal part of the femur

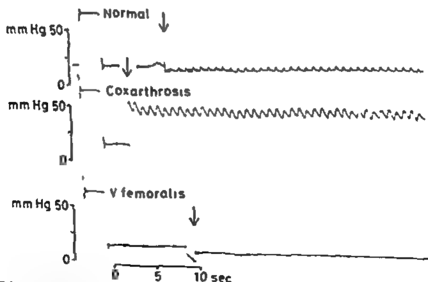

Fig 6 Bilateral measurements of intraosseous pressure in the femoral neck with simultaneous recording of femoral vein pressure Patient with unilateral coxarthrosis

As previously described, it is possible to distinguish between a proliferative and a fibrous type of synovitis in coxarthrosis. By comparing the ratios of the four proteins in these two types it was found that patients with proliferative synovitis showed higher SF/S ratios than those with fibrous synovitis. The difference was significant for α_2-macroglobulin ($p<0.01$). Thus the abnormal protein pattern in osteoarthritic synovia reflects an increased capillary permeability in the synovial membrane and it seems to correlate with the histological features.

Discussion

Swelling and pain are regular features in all inflammatory joint disease, typified by rheumatoid arthritis. It is also a common symptom after trauma or overloading, more easily noticed, e.g. in the knee than in the hip joint. The patient with primary coxarthrosis is generally in his late fifties or sixties when he is seen by the orthopaedic surgeon. However, a careful history will often reveal periods of intermittent pain in the hip region, combined with limping, during the years preceding the state of manifest osteoarthritis. During this period, when the X-rays are normal, the patients are rarely seen by the orthopaedic surgeon, but by their family physician or a rheumatologist. The treatment – if any – is conservative, mainly consisting of rest, occasionally combined with physical treatment of various kinds, and during the recent decade medication with one or several of the non-steroid antiphlogistica. This conservative regimen is often effective, but in some cases the symptoms return periodically until the diagnosis osteoarthritis becomes obvious. This conservative treatment is essentially a treatment of synovitis.

Thus, there are clinical indications that even primary coxarthrosis does not appear suddenly and without warning sometime after the fifty-fifth birthday. The history is more likely to suggest that clinical osteoarthritis is the final stage of a fairly long-lasting joint disorder. Our clinical experience suggests that many attacks of synovitis disappear without doing permanent damage to the joint. In certain cases the attack leads to manifest coxarthrosis within a short period of time, but in most cases of primary coxarthrosis the synovitic episodes stretch over a number of years before the typical roentgen changes become visible.

Inflammation, joint effusion and subsequent stasis result in a vascular derangement in the synovial membrane. *Increased capillary permeability is followed by a change in the protein* pattern and the amount of protein in the synovia. One of the functions of the synovial fluid is joint lubrication. As shown by Reimann et al. (1975) and Reimann (1976) boundary lubrication is reduced in rheumatoid arthritis and osteoarthritis. It seems probable that this deterioration is due to the change in the protein pattern of the synovial fluid.

The increased production of acid phosphatase and lysosomes, known to be of importance for the degenerative changes of articular cartilage, and the reduction of oxygen in the synovial fluid (Lund-Olesen 1970) are of special importance as the synovia is the vehicle for supply of oxygen and nutrition to the cartilage. Further, decreased oxygen tension is of significance for release of lysosomal enzymes (de Duve 1964).

The mechanical effect of synovitic joint effusion is discussed on p. 21.

VASCULAR CHANGES IN JUXTAARTICULAR BONE MARROW

The fact that degenerative changes usually are caused by a failure in the supply of oxygen and nutrition to the tissues involved focussed attention on the state of the arterial supply to the joint in many early studies on osteoarthritis As late as the middle of this century many authors were of the opinion that osteoarthritis of the hip was accompanied or preceded by a state of ischaemia of sub- and juxtachondral bone (Wollenberg 1909, Goldhaft et al 1930, Phemister 1940, Pridie 1952) This conception was challenged by Harrison et al (1953) By means of injection studies on cadavers they found a hyperplasia of the intraosseous arteries in the femoral head, and on the basis of this observation they assumed that the arterial inflow to the femoral head was increased instead of reduced in coxarthrosis The same authors also found signs of venous stasis in the bone marrow

In the years following this study investigations by means of intraosseous phlebography provided evidence of disturbed venous outflow from the femoral head and neck in patients with coxarthrosis and from the distal part of the femur in patients with gonarthrosis (Ménel et al 1955, Hulth 1959, Helal 1962, Wardle 1964, Phillips 1966) and increased intramedullary pressure in juxtachondral bone marrow (Arlet et al 1968)

Own investigations

Intraosseous phlebography and measurements of intraosseous pressure

Coxarthrosis In a series of 15 patients with unilateral painful primary osteoarthritis of the hip joint, Arnoldi et al (1972 a) measured the pressure in the bone marrow of both femoral necks and the femoral vein These examinations were followed by bilateral serial intraosseous phlebography of the proximal part of the femur

The mechanical effect of synovitic joint effusion is discussed on p 21

Fig 8 Exposures of the same patient as in Fig 7 The film of the normal hip was exposed three minutes after the injection of contrast The exposure of the hip with osteoarthritis was made thirty minutes later Large quantities of contrast are left in the medullary space

In a second series of pressure measurements the same authors showed 5) that in patients with coxarthrosis the intraosseous pressure was always higher in the femoral head than in the neck (mean difference 10 [illegible] mmHg)

In another study Arnoldi et al (1971) found that 6) in patients with coxarthrosis intertrochanteric osteotomy or cortical fenestration caused an immediate fall of intramedullary pressure in the femoral head and neck (osteotomy 17 [illegible] mmHg and 13 5 mmHg respectively fenestration 21 5 mmHg and 15 9 mmHg respectively (mean values)) (Fig 9) In 10 of the 11 patients who complained of rest pain before the operation these pains had disappeared within 24 hours after the operation

Thus these investigations showed that patients with *late* stages of *painful* coxarthrosis invariably suffered from intraosseous venous stasis and hypertension in the bone marrow of the proximal femur and the changes were most pronounced near the hip joint The pressure in the extraosseous and extracapsular veins was not affected Later investigations have shown the same findings in patients with various forms of painful secondary coxarthrosis

They observed that 1) the intraosseous pressure in normal bone marrow was always higher than the pressure in the extraosseous veins of the region (mean difference 6 8 mmHg) 2) The intraosseous pressure was always higher in the arthritic hip than in the healthy hip (mean difference 29 7 mmHg) (Fig 6) 3) High intraosseous pressure coincided with phlebographic signs of impaired venous drainage from the upper end of the femur (intramedullary retention of contrast material and disappearance of the veins draining the femoral head (vv retinaculares) (Fig 7 and Fig 8) 4) Patients with high intraosseous pressures (<40 mmHg) always complained of characteristic pain at rest while patients with lower pressures did not suffer from this symptom

Fig 7 Bilateral intraosseous phlebography from patient with unilateral coxarthrosis exposed thirty seconds after bilateral injection of 8 millilitres Isopaque Cerebral In the normal hip the contrast material leaves the intraosseous space without noticeable filling of intraosseous vessels and is observed in the normal drainage veins In the hip with severe osteoarthritis the contrast is seen in large tortuous intraosseous veins extending far down into the femoral shaft

Fig 10 Hip joint from patient with the intraosseous engorgement pain syndrome after fenestration of the femoral neck

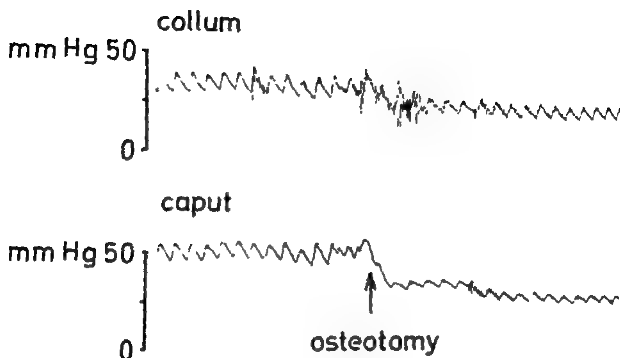

Fig 9 Pressure tracing from the femoral head and neck, before and after subtotal intertrochanteric osteotomy

The intraosseous engorgement-pain syndrome The finding that the characteristic rest pain of coxarthrosis seemed to be connected with intraosseous venous stasis and hypertension focussed our attention on this symptom

In a series of investigations on patients with various painful conditions in the knee region Arnoldi et al (1975) found that patients with rest pain (with or without osteoarthritis) showed a higher intraosseous pressure in the proximal part of the tibia or the lower part of the femur than patients without rest pain (with or without osteoarthritis) They observed that the patients with rest pain and high intraosseous pressure, but without visual or clinical signs of osteoarthritis, generally belonged to a younger age group than patients with gonarthrosis Later studies of this condition (Lemperg & Arnoldi 1978, Arnoldi et al in press 1979 b), showed that the high pressures were accompanied by intraosseous venous stasis, that the intraosseous engorgement-pain syndrome could be located to the hip as well as to the knee region (Fig 10 and 11), and that roentgen examination often showed a state of juxtaarticular osteopenia in these patients instead of the sclerotic appearance characteristic of osteoarthritis

inhibit the function of the quadriceps femoris muscle and lead to atrophy and flexion contracture (De Anrade et al 1965)

In human coxarthrosis the habitual contracture is flexion, outward rotation and adduction, which is also the position with the greatest joint volume due to maximal relaxation of the fibrous capsule One of the very early clinical signs of coxarthrosis and the intraosseous engorgement pain syndrome is pain on inward *rotation in flexion If this symptom* is analysed carefully it becomes obvious that the pain increases with increasing rotation The movement from maximum inward rotation back into neutral is accompanied by relief of pain Inward rotation reduces the volume of the hip joint and if effusion is present the intraarticular pressure should reach its maximum in this position

INTERDEPENDENCE BETWEEN INTRAARTICULAR AND INTRAOSSEOUS PRESSURE

Theoretically intraosseous stasis and hypertension could be explained as the effect of blockage of flow through the draining vessels from the weight bearing area of the femoral head, and the haemodynamic changes in the bone marrow might be secondary to high pressure in the joint cavity due to synovitic effusion

Own investigations

Although the circumstantial evidence of interdependence between intraarticular and intraosseous pressure is impressive, direct experimental evidence of this relationship has been lacking In order to investigate the reaction of intraosseous pressure to variations in intraarticular pressure we measured the pressure in the bone marrow of the femoral condyle of healthy rabbits before, during and after a known rise of pressure in the knee joint (Arnoldi et al 1979 b)

As in human subjects the intraosseous pressure is normally somewhat higher than the intraarticular pressure Injection of fluid into the knee joint was accompanied by an immediate rise of intraarticular pressure and followed by a *slower rise of* pressure in the bone marrow of the femoral condyle (Fig. 12 and Fig 13) The results indicated a blockage of venous outflow through the intraarticular drainage vessels with continued arterial inflow to the bone marrow

Fig 11 ^{99m}Tc polyphosphate scintigraphy of both hips from the patient shown in Fig 10 (before operation)

Discussion

The cause of intraosseous stasis and hypertension

Our findings by means of intraosseous and intravenous pressure measurements in patients with coxarthrosis indicate that the blockage of venous drainage from the femoral head is located somewhere in or just outside the cortex Pressure measurements from extraosseous and extracapsular veins including the circumflex veins have shown normal findings (Fig 6 and Fig 22) The observations by Phillips et al (1967) seem to exclude venous thrombosis as a cause of blockage They found that intraosseous phlebography repeated 12 20 months after intertrochanteric osteotomy showed reopening of the normal drainage vessels from the femoral head in a number of patients Their phlebograms show no signs that this reopening was due to recanalisation of thrombosed veins

The retinacular veins leave the femoral head just distal to the cartilage border and until they join the circumflex veins their course is intraarticular The pressure in these veins lies between about 10 mmHg (the pressure in the normal bone marrow) and 5 mmHg (the pressure in the large extraosseous veins) As the studies on the synovium indicated and as direct measurements from other joints have shown (Eyring & Murray 1964) the intraarticular pressure increases when the volume of synovia increases or when the joint space is reduced A rise of intraarticular pressure in the order of 10 to 15 mmHg is sufficient to impede the flow through the intraarticular veins unless the perfusion pressure is raised

Contracture, joint volume and pain

From experiments on patients with rheumatoid arthritis of the knee joint we know that in the presence of joint effusion the intraarticular pressure is least in the mildly flexed position (Favreau & Laurin 1963 Eyring & Murray 1964 Jayson & Dixon 1970) which is the position spontaneously adopted by patients with effusions in the knee joint and gives least discomfort (Eyring & Murray 1964) In these experiments it was shown that further flexion of the knee produced extremely high intraarticular pressures that actually could rupture the joint capsule Further high intraarticular pressure could

inhibit the function of the quadriceps femoris muscle and lead to atrophy and flexion contracture (De Anrade et al 1965)

In human coxarthrosis the habitual contracture is flexion, outward rotation and adduction, which is also the position with the greatest joint volume due to maximal relaxation of the fibrous capsule One of the very early clinical signs of coxarthrosis and the intraosseous engorgement pain syndrome is pain on inward rotation in flexion If this symptom is analysed carefully it becomes obvious that the pain *increases with increasing rotation* The movement from maximum inward rotation back into neutral is accompanied by relief of pain Inward rotation reduces the volume of the hip joint and if effusion is present the intraarticular pressure should reach its maximum in this position

INTERDEPENDENCE BETWEEN INTRAARTICULAR AND INTRAOSSEOUS PRESSURE

Theoretically intraosseous stasis and hypertension could be explained as the effect of blockage of flow through the draining vessels from the weight bearing area of the femoral head, and the haemodynamic changes in the bone marrow might be secondary to high pressure in the joint cavity due to synovitic effusion

Own investigations

Although the circumstantial evidence of interdependence between intraarticular and intraosseous pressure is impressive, direct experimental evidence of this relationship has been lacking In order to investigate *the reaction* of intraosseous pressure to variations in intraarticular pressure we measured the pressure in the bone marrow of the femoral condyle of healthy rabbits before, during and after a known rise of pressure in the knee joint (Arnoldi et al 1979 b)

As in human subjects the intraosseous pressure is normally somewhat higher than the intraarticular pressure Injection of fluid into the knee joint was accompanied by an immediate rise of intraarticular pressure and followed by a *slower rise* of pressure in the bone marrow of the femoral condyle (Fig 12 and Fig 13) The results indicated a blockage of venous outflow through the intraarticular drainage vessels with continued arterial inflow to the bone marrow

Fig 11 ^{99m}Tc-polyphosphate scintigraphy of both hips from the patient shown in Fig 10 (before operation)

Discussion

The cause of intraosseous stasis and hypertension

Our findings by means of intraosseous and intravenous pressure measurements in patients with coxarthrosis indicate that the blockage of venous drainage from the femoral head is located somewhere in or just outside the cortex Pressure measurements from extraosseous and extracapsular veins, including the circumflex veins, have shown normal findings (Fig 6 and Fig 22) The observations by Phillips et al (1967) seem to exclude venous thrombosis as a cause of blockage They found that intraosseous phlebography repeated 12-20 months after intertrochanteric osteotomy showed reopening of the normal drainage vessels from the femoral head in a number of patients Their phlebograms show no signs that this reopening was due to recanalisation of thrombosed veins

The retinacular veins leave the femoral head just distal to the cartilage border and until they join the circumflex veins their course is intraarticular The pressure in these veins lies between about 10 mmHg (the pressure in the normal bone marrow) and 5 mmHg (the pressure in the large extraosseous veins) As the studies on the synovium indicated, and as direct measurements from other joints have shown (Eyring & Murray 1964), the intraarticular pressure increases when the volume of synovia increases or when the joint space is reduced A rise of intraarticular pressure in the order of 10 to 15 mmHg is sufficient to impede the flow through the intraarticular veins, unless the perfusion pressure is raised

Contracture, joint volume and pain

From experiments on patients with rheumatoid arthritis of the knee joint we know that in the presence of joint effusion the intraarticular pressure is least in the mildly flexed position (Favreau & Laurin 1963, Eyring & Murray 1964, Jayson & Dixon 1970) which is the position spontaneously adopted by patients with effusions in the knee joint and gives least discomfort (Eyring & Murray 1964) In these experiments it was shown that further flexion of the knee produced extremely high intraarticular pressures that actually could rupture the joint capsule Further, high intraarticular pressure could

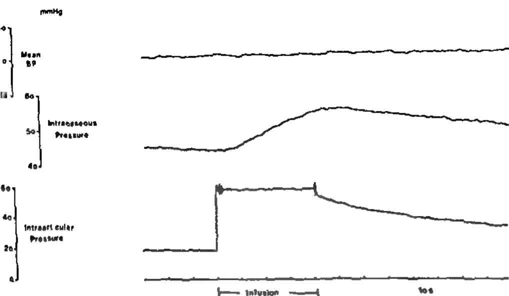

Fig 13 Tracing of intraosseous pressure increase induced by joint infusion of saline Simultaneous pressure curves from a single experiment

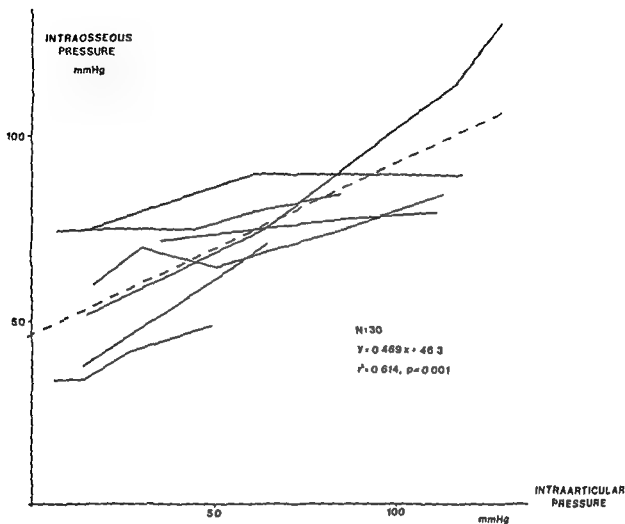

Fig 12 Intraosseous pressure as a function of intraarticular pressure A rise of intraarticular pressure resulted in a significant rise of pressure in juxtaarticular bone marrow ($p<0\ 001$)

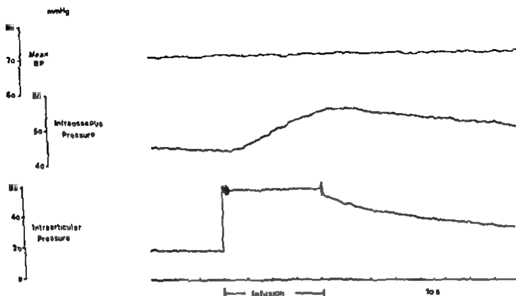

Fig 13 Tracing of intraosseous pressure increase induced by joint infusion of saline Simultaneous pressure curves from a single experiment

Discussion

The experiments described above indicate that intraosseous stasis and hypertension may in fact be secondary to a joint effusion with high intraarticular pressure caused by synovitis

CHANGES IN SUBCHONDRAL BONE

The structural changes in subchondral bone in the osteoarthritic femoral head are fairly well known (Collins 1949, Sokoloff 1969, Radin et al 1970, Foss & Byers 1972, Jeffrey 1973) Roughly, they are characterized by an attempt to repair dead trabeculae with increased bone formation The macroscopic results are seen as deformation of the head, cyst formation, increased radiodensity and building of osteophytes

Own investigations

Quantitative histological analysis of articular cartilage and subchondral bone

In order to quantify the alterations in subchondral bone and to compare the changes with the severity of the cartilage lesions, a quantitative histological analysis of articular cartilage and subchondral bone from osteoarthritic and normal human hips was performed (Reimann et al 1977)

The analysis was based on 12 femoral heads, six osteoarthritic and six controls The cartilage was graded according to the histological-histochemical system of Mankin et al (1971), using the Safranin O staining method The subchondral bone was analysed to establish the percentage of trabecular, osteoblastic and osteoclastic areas The trabecular bone area measurements were made with point-counting method (Harris & Weinberg 1972) and for osteoblastic and osteoclastic area counts the technique described by Melsen et al (1975) was used

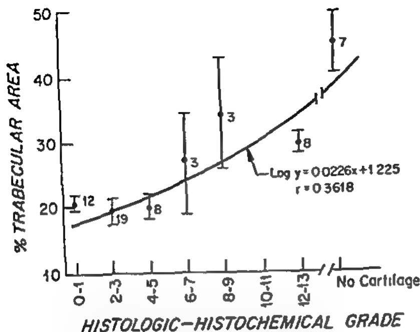

Fig 14 Diagram illustrating the relationship between the histological histochemical grade and the per cent of trabecular area

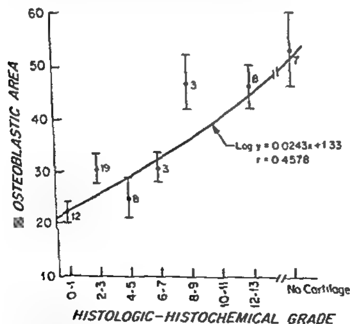

Fig 15 Diagram showing the relationship between histological-histochemical grade and the per cent of osteoblastic area

Discussion

The experiments described above indicate that intraosseous stasis and hypertension *may in fact be* secondary to a joint effusion with high intraarticular pressure caused by synovitis

CHANGES IN SUBCHONDRAL BONE

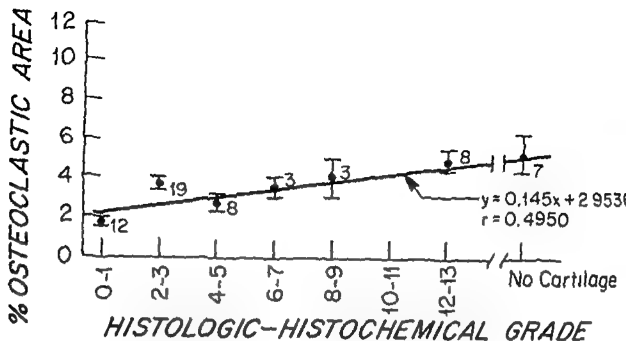
Fig 17 Radiographs of femoral head with osteoarthritis showing the different areas estimated The figures below illustrate the variations in the initial time according to the site studied

Frozen sections from 24 osteoarthritic femoral heads were prepared for semiquantitative analysis of the enzyme activity using Burstone s (1959) and Barka & Anderson s (1963) enzymo-histochemical methods The analyses showed that there were wide variations within the same femoral head for both enzymes with significantly higher activity in weight bearing than in non weight bearing areas and in subchondral bone compared with more central areas (Fig 17) Further the enzyme activity correlated directly with the severity of the cartilage lesions The findings seemed to be consistent with the morphological findings in the histological study

Distribution of ^{99m}Tc-phosphate compounds in osteoarthritic femoral heads (Christensen & Arnoldi in press 1979)

Femoral heads from 12 patients with osteoarthritis were examined Ten mCi ^{99m}Tc phosphate was given intravenously approximately 2 hours before total hip replacement and frozen sections were prepared Autoradiograms showed accumulation of ^{99m}Tc phosphate in the subchondral region of the weight bearing area of the femoral head and in the osteophytes (Fig 18 A and B) In the weight bearing area the uptake was particularly high in the walls of the cysts In the osteophytes the radionuclide was localized at the osteochondral junction



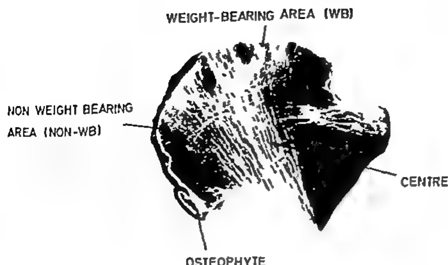


Fig 16 Graphic representation illustrating the relationship between histological histochemical grade and per cent of osteoclastic area

The data obtained showed wide variations in all parameters in the osteoarthritic specimens, but consistently more marked alterations in the weight bearing areas The trabecular bone area as well as osteoblastic and osteoclastic areas were significantly larger in the osteoarthritic than in the control group (normal femoral heads obtained at autopsy or femoral heads removed after fracture of the femoral neck) (Fig 14, Fig 15 and Fig 16) By comparing the bony changes with the severity of the cartilage lesions from different areas within the same femoral head a correlation of moderate significance was found between the degeneration of the cartilage and sclerosis and hypermetabolism of the subchondral bone

Histochemical study of alkaline and acid phosphatase activity

To further elucidate the metabolic changes found in the subchondral osteoarthritic bone by histological examination a histochemical investigation was performed (Reimann & Christensen 1979)

Alkaline phosphatase was used as a marker enzyme for bone regeneration and acid phosphatase as a marker enzyme for bone resorption These enzymes were chosen as increased alkaline phosphatase activity has been demonstrated in regions of deposition of new bone (Jeffree 1959 Jeffree & Price 1965, Timmer et al 1968, Andersen 1970) and acid phosphatase – associated with the lysosomes in the osteoclasts – plays an important role in bone resorption (Burstone 1959 Doty & Scofield 1976)

Distribution of ^{99m}Tc-phosphate compounds in osteoarthritic femoral heads (Christensen & Arnoldi in press 1979)

Femoral heads from 12 patients with osteoarthritis were examined Ten mCi ^{99m}Tc phosphate was given intravenously approximately 2 hours before total hip replacement and frozen sections were prepared Autoradiograms showed accumulation of ^{99m}Tc phosphate in the subchondral region of the weight bearing area of the femoral head and in the osteophytes (Fig 18 A and B) In the weight bearing area the uptake was particularly high in the walls of the cysts In the osteophytes the radionuclide was localized at the osteochondral junction

ɪg 18 A *Autoradıogram from osteoarthrıtıc femoral head from a patient given ^{99m}Tc polyphosphate preoperatıvely The radıonuclıde ■ predomınantly accumulated at the cyst wall of the weıght bearıng area and at the osteochondral junctıon ın the osteophytes*

B *Correspondıng roentgenogram of a thın slıce of the femoral head*

A quantıtatıve study was performed from sıx dıfferent zones on ■ 10-mıcron thıck sectıon from each emoral head, the sıx zones beıng the weıght bearıng area, the non weıght bearıng area, the ɔsteophytes, the central area, the synovıal membrane and the fibrous capsule These dıfferent zones were counted ın a well counter The areas were determıned by planımetry and the uptake per unıt olume was expressed ın proportıon to the uptake per unıt volume ın the fibrous capsule The quantıtatıve study confirmed the ımpressıon from the autoradıograms Thus, the hıghest uptake was ın he weıght bearıng area and ın the osteophytes and the lowest ın the synovıal membrane and fibrous capsule (Fıg 19)

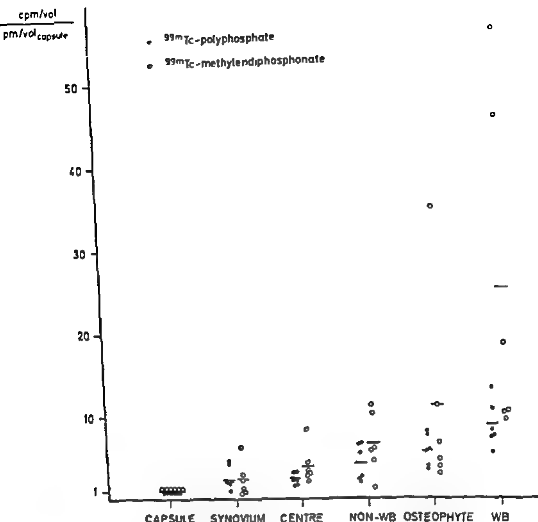

Fig 19 Target to-background ratio on different areas in twelve osteoarthritic femoral heads, using the uptake of radionuclide in the fibrous capsule as background

To compare the distribution of the radionuclide with the morphology, sections were stained with haematoxylin-eosin with the van Kossa technique for calcium phosphate and by Burstone's method for determination of alkaline phosphatase activity (Fig 20 A, B and C) The morphological studies showed that the radionuclide accumulated in areas of new bone formation, particularly enchondral ossification Histochemical staining for alkaline phosphatase activity showed that the distribution of this enzyme roughly corresponded to the deposition of the bone-seeking radionuclide Incidentally, these investigations failed to produce evidence of callus formation in microfractures of subchondral bone trabeculae

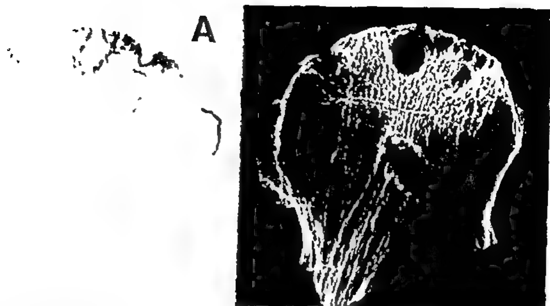

Fig 18 A: *Autoradiogram from osteoarthritic femoral head from a patient given* ^{99m}*Tc polyphosphate preoperatively The radionuclide is predominantly accumulated at the cyst wall of the weight-bearing area and at the osteochondral junction in the osteophytes*
B *Corresponding roentgenogram of a thin slice of the femoral head*

A quantitative study was performed from six different zones on a 10-micron thick section from each femoral head, the six zones being the weight-bearing area, the non-weight-bearing area, the osteophytes, the central area, the synovial membrane and the fibrous capsule These different zones were counted in a well-counter The areas were determined by planimetry and the uptake per unit volume was expressed in proportion to the uptake per unit volume in the fibrous capsule The quantitative study confirmed the impression from the autoradiograms Thus, the highest uptake was in the weight-bearing area and in the osteophytes and the lowest in the synovial membrane and fibrous capsule (Fig 19)

Fig 21 ^{99m}Tc-polyphosphate scintigraphy from patient with unilateral painful coxarthrosis Compare Fig 11

The authors concluded that the results may be an indication that the intraosseous engorgement pain syndrome and osteoarthritis are two stages of the same pathological process

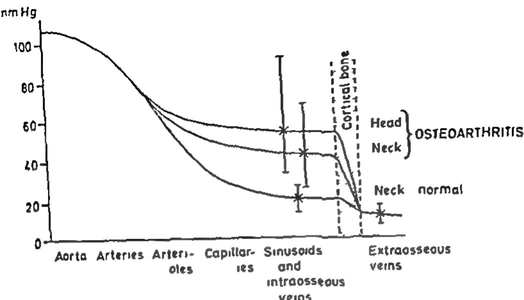

Fig 22 Schematic representation of intraosseous and extraosseous pressures in patients with unilateral painful coxarthrosis

Discussion

The conditions for capillary flow in the femoral head in coxarthrosis

Fig 22 shows intramedullary and intravenous pressures from patients with unilateral coxarthrosis, together with mean arterial blood pressure measured on the upper arm The findings are inserted into a Landis curve of pressure distribution through the vascular system (Arnoldi et al 1972 a) The rate of flow through the capillary depends upon the diameter of the vessel and upon the pressure difference between the arterial and venous end of the capillary As seen in Fig 22 this pressure difference decreases in coxarthrosis and more so in the femoral head than in the neck Hyperplasia of the intramedullary arteries as demonstrated by Harrison et al (1953) may be a compensatory reaction to the high resistance to flow on the venous side of the circulation With a pressure distribution as shown in Fig 22 the end result is probably a reduced nutritional flow to bone tissue especially to the subchondral bone of the weight bearing area of the femoral head The slow clearance of radioactive NaI from the bone marrow of the femoral head demonstrated by Hernborg (1969) may be an indication of this state

There is however both clinical and experimental evidence that the intraosseous pressure – and thus the resistance to capillary flow – may vary considerably with circumstances If – as our findings induce us to believe – the characteristic rest pain is caused by excessively high pressure in the bone marrow, the appearance of pain after exercise and disappearance after a period of rest indicate variations of pressure depending upon activity Fig 23 illustrates the effect of prolonged bed rest upon the marrow pressure

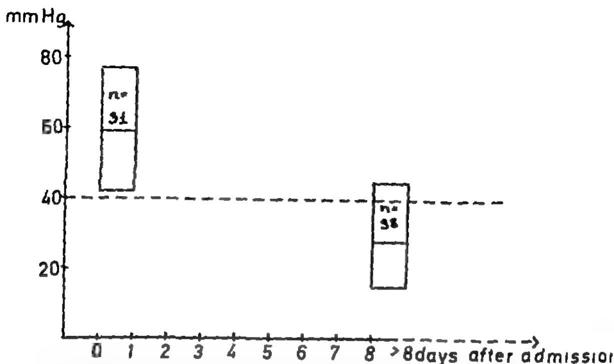

Fig 23 Intraosseous pressures from the femoral neck of hip joints with coxarthrosis and a history of severe aching rest pains Data from 69 hips Pressure in mmHg, means and range 31 hips examined within 24 hours after the patient was admitted to hospital, 38 examined after 8-22 days bed rest

Fig 22 indicates that under extreme circumstances the blood flow through subchondral bone marrow may virtually be at a stand still The effect upon cellular nutrition would be very much the same as blockage at the arterial end of the system Complete blockage of arterial inflow to bone results in death of the osteocytes within 8 to 24 hours (Rosingh & James 1969) Thus, clinical observations as well as experimental findings indicate considerable periodical variations in the amount of oxygen available to the cells in the femoral head

The effect of reduced nutritive capillary flow on the bone structure of the femoral head

The finding of Hernborg (1969) of a reduced clearance of radioactive NaI from the femoral head in osteoarthritis and the intraosseous stasis and hypertension demonstrated by others indicate a reduced blood flow through the bone marrow of the femoral head in spite of continued arterial inflow This would most probably result in a reduced PO_2 in the region Direct measurements of oxygen tension in the bone marrow are surprisingly few, but some evidence of reduced oxygen tension has been presented (Brookes 1970, Pujol et al 1973)

The histological picture of juxtaarticular bone in coxarthrosis is a mixture of bone death and new bone formation Several authors are of the opinion that venous stasis and reduced oxygen tension are the factors responsible for new bone formation (Harrison et al 1953, Pistolesi 1962 Abdalla & Harrison 1966, Phillips et al 1967, Arnoldi et al 1972 b) The investigations reported here indicate that the various phases of bone death and new bone formation might correlate with varying conditions for

cellular nutrition which in their turn are dependent upon varying degrees of resistance to flow from the drainage vessels of the weight bearing area of the femoral head

Our investigations point to the weight bearing area as the place where the changes from normal are most pronounced We are convinced that mechanical factors play an important role in the deformation of the joint that is so obvious in coxarthrosis However not all these features are directly explained by the effect of mechanical forces (e g osteophytes) Our investigations also stress the fact that the weight bearing area is the part of the femoral head that is drained by the superior retinacular veins and the part where the effects of venous stasis are most pronounced In our opinion the question of the relative importance of mechanical forces and weakening of bone structure due to circulatory deficiency for the deformation seen in osteoarthritic joints is still unanswered Theoretically it is quite feasible to assume that mechanical forces are only able to cause deformation of a joint if they act upon tissues previously weakened by degenerative changes produced by circulatory derangement

Are the vascular changes in subchondral bone marrow an early or late factor in the development of coxarthrosis?

Intraosseous stasis and high pressure in the vessels of the subchondral bone marrow are generally regarded as late and secondary manifestations of coxarthrosis which can be explained as a consequence of cartilage and bone changes (Freeman 1972) It is true that demonstration of vascular changes in the late stages of coxarthrosis does not necessarily indicate that these changes initiated the process leading to clinical osteoarthritis

However several well known clinical facts combined with recent findings indicate that haemodynamic changes in juxtaarticular bone may – after all – be a very early and perhaps causative factor in the development of the *skeletal* changes characteristic of osteoarthritis

1) The clinical observation that synovitis is a very common precursor to clinical osteoarthritis combined with the finding that increased intraarticular volume and pressure is followed by an increase of pressure in juxtaarticular bone marrow (Arnoldi et al 1979 a)
2) The experimental findings by Abdalla & Harrison (1966) that marrow stasis and high intramedullary pressure produced radiological and histological changes in cartilage and subchondral bone in albino rats that were consistent with those of human osteoarthritis
3) The observation that long standing ambulatory hypertension in patients with chronic venous insufficiency leads to skeletal changes of the same character as seen in osteoarthritis (Arnoldi et al 1972 b)
4) The observation that intraosseous stasis and hypertension may be observed in younger people with synovitis and pain but without signs of cartilage destruction (the intraosseous engorgement pain syndrome)

ARTICULAR CARTILAGE

The changes of articular cartilage in osteoarthritis are progressive with advancing disease leading to complete loss of tissue Most investigators are of the opinion that "degeneration" of this tissue is primary in the pathogenesis of osteoarthritis Over the years a sizable part of the literature has been

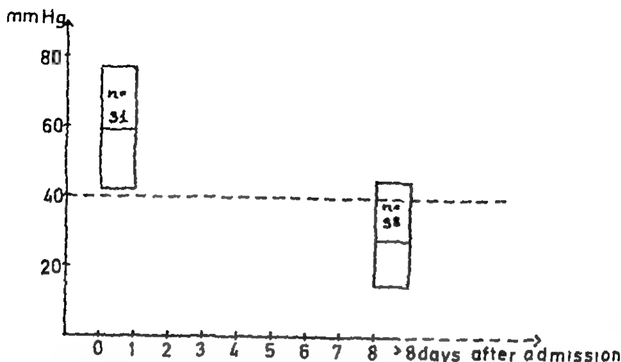

Fig 23 Intraosseous pressures from the femoral neck of hip joints with coxarthrosis and a history of severe aching rest pains Data from 69 hips Pressure in mmHg, means and range 31 hips examined within 24 hours after the patient was admitted to hospital, 38 examined after 8-22 days bed rest

ARTICULAR CARTILAGE

The changes of articular cartilage in osteoarthritis are progressive with advancing disease leading to complete loss of tissue Most investigators are of the opinion that "degeneration" of this tissue is primary in the pathogenesis of osteoarthritis Over the years a sizable part of the literature has been

concerned with attempts to analyse these changes It is not our intention to review this literature as extensive treatises on the subject are available (e g Sokoloff 1969)

Numerous reports have been concerned with investigations of biochemical changes in the matrix of articular cartilage and a reduction in the amount of glycosaminoglycans, as well as alterations in quality, have been consistent findings in osteoarthritis (Mathews & Glagov 1966, Mankin & Lippiello 1970 and 1971, Bjelle et al 1972, Lust & Pronsky 1972 and many others), but parallel with this reduction an increased synthesis of glycosaminoglycans was observed when $^{35}SO_4$ was incorporated (Collins & McElligot 1960, Mankin et al 1971, Eronen et al 1978)

The histological changes in osteoarthritis are characteristic (Collins 1949, Harrison et al 1953, Sokoloff 1969, Mankin et al 1971 and others) and a histological histochemical grading system (Mankin et al 1971) is available It has been shown that this grading system correlates with biochemical (Mankin et al 1972) as well as with enzyme abnormalities (Ehrlich et al 1973) in the cartilage

Own investigations

We have used this grading system to define the severity of the changes in articular cartilage from osteoarthritic femoral heads in various studies of the subchondral bone in order to compare the alterations in cartilage and subchondral bone (Reimann et al 1977, Reimann & Christensen 1979)

Differential histochemical staining of glycosaminoglycans in osteoarthritic cartilage

In another study (Christensen & Reimann, in Press) we performed a histochemical analysis of articular cartilage from osteoarthritic femoral heads, using Safranin 0, Alcian Blue CEC and Toluidine Blue at different pH values The purpose of the study was to demonstrate the presence and amount of chondroitin sulphate and keratan sulphate in the cartilage matrix and its distribution compared with normal cartilage

Safranin 0 was used to classify the degree of the osteoarthritic changes in cartilage according to the grading system of Mankin et al (1979) Alcian Blue with critical electrolyte concentration principle (Scott & Dorling 1965) was used to differentiate chondroitin 4/6 sulphate from keratan sulphate (Laurent & Scott 1964, Scott 1967) Toluidine Blue at different pH values is a metachromatic staining and as shown by Krygier & Kasprzyk (1961) and Spicer (1962) persisting metachromasia at pH 1 5 indicates presence of sulphated glycosaminoglycans while carboxyl groups lose their metachromasia at pH 3

These investigations showed that the degree of cartilage degeneration in osteoarthritis varied considerably from site to site within the same femoral head Pronounced changes were seen in weight bearing areas whereas less severe changes were present in non weight bearing areas Reduction in staining ability was seen first and most distinctly at the surface Apart from the loss of staining for glycosaminoglycans the osteoarthritic cartilage was characterized by increased territorial staining of chondroitin sulphate (Alcian Blue with 0 4 M $MgCl_2$) especially round cell clusters (Fig 24 A and B) Further, keratan sulphate was found to be located more basically than chondroitin sulphate In the cartilage of osteophytes practically only chondroitin sulphate was present The increased territorial staining of chondroitin sulphate reflects an accelerated synthesis possibly an attempt to repair as seen in immature cartilage

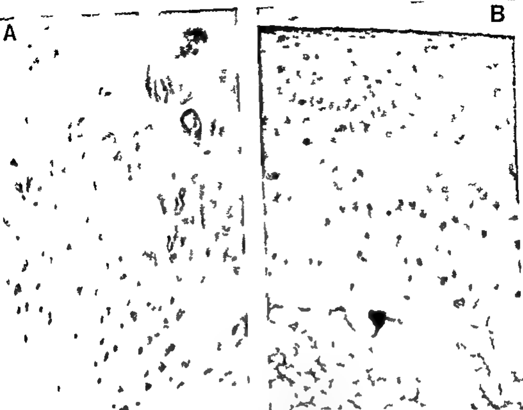

Fig 24 A *Osteoarthritic cartilage from a patient aged 50 years with intense territorial staining especially high around cell clusters Alcian Blue with 0 4 M $MgCl_2$ Magnification x 100*

B *Articular cartilage from a patient aged 73 with fracture of the femoral neck Alcian Blue with 0 4 M $MgCl_2$ Magnification x 100*

Aetiology and time factor

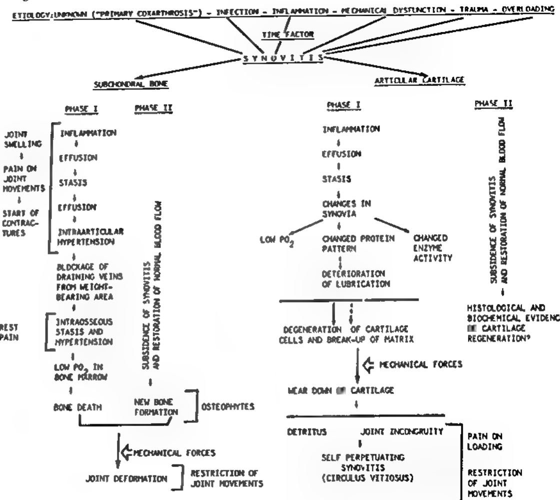
The investigations reported here have mainly been concerned with the pathomechanism of "primary" or "idiopathic" coxarthrosis and the intraosseous engorgement-pain syndrome. However, intraosseous pressure measurements and phlebography have been performed on a considerable number of patients

Discussion

The choice of our investigations on articular cartilage from human osteoarthritic femoral heads was largely determined by our resources and have first and foremost been an attempt to determine whether a relationship exists between changes in cartilage and subchondral bone Such a relationship has been suggested by means of biomechanical considerations (Radin et al 1973, Pugh et al 1974) and demonstrated as described above by quantitative histological analyses (Reimann et al 1977) Further, it has been shown that the histological changes from osteoarthritic femoral heads, evaluated by the grading system of Mankin et al (1971), correlate with biochemical and enzyme abnormalities of the osteoarthritic cartilage (Ehrlich et al 1973) In our studies these correlations were most pronounced in the weight-bearing area

Articular cartilage has no blood vessels of its own Most investigators are of the opinion that cartilage is supplied with oxygen and nutrition through the vessels of the synovium via the synovial fluid and that the subchondral intraosseous vessels are of little importance in this respect

As discussed previously, inflammation and stasis in the synovium reduce the rate of flow through the synovial vessels and increase the permeability of the capillary wall One result of these changes is a lowering of oxygen tension in the synovial fluid (Lund Olesen 1970) The protein and enzyme patterns are altered (see above) and striking changes in glycogen metabolism have been noted (Treuhaft & McCarty 1971, Lane et al 1977) At the same time the lubricating function of the synovia probably is impaired (Reimann 1976)



These changes in cartilage environment seem to us a reasonable – if still theoretical – cause of the changes observed in cartilage cells and matrix Mechanical forces undoubtedly play an important part in the wear and tear that leads to tissue waste, but – as was the case in the question of changes in subchondral bone – we find it difficult to accept mechanical forces as primary causes of cartilage damage To us the clinical course of osteoarthritis as well as the experimental evidence suggest that mechanical force is only able to damage cartilage that is weakened by other causes

The evidence of our own investigations indicates that the changes observed in articular cartilage and subchondral bone are parallel reactions to the same primary pathological process

GENERAL DISCUSSION

The findings in patients with osteoarthritis and the engorgement pain syndrome by means of intraosseous phlebography and pressure measurements combined with the results of a series of studies on the effects on the mesenchymal tissues of the ankle region of dysfunction of the venous pump of the calf in patients with chronic venous insufficiency (Arnoldi 1964 Arnoldi & Linderholm 1971) especially the changes of the ankle skeleton and joint (Arnoldi et al 1972 b) led to the working hypothesis sketched in Fig 1 The results of the studies reported here and reports from the literature are *tentatively* correlated in the hypothesis shown in Fig 25

Fig 25

Aetiology and time factor

The investigations reported here have mainly been concerned with the pathomechanism of "primary" or idiopathic coxarthrosis and the intraosseous engorgement pain syndrome. However, intraosseous pressure measurements and phlebography have been performed on a considerable number of patients

with coxarthrosis secondary to rheumatoid arthritis, Legg Calvé Perthe's disease and trauma, and painful secondary coxarthrosis after these disorders shows the same intraosseous stasis and hypertension as found in idiopathic coxarthrosis We therefore assume the pathomechanism to be more or less identical in primary and most forms of secondary coxarthrosis Their clinical course may be strikingly different, ranging from the silent period between the congenital hip dislocation and the appearance of clinical osteoarthritis decades later to the rapid development of secondary coxarthrosis after trauma or rheumatoid arthritis *These "time factor" differences have probably something to do* with the severity of the aetiological factor Apart from the specific effect of the rheumatoid inflammation on, e g the enzyme activity in the joint, patients with rheumatoid arthritis show the lowest synovial oxygen tension measured As mentioned above we believe primary coxarthrosis to be the end result of a series of attacks of synovitis, sometimes stretching over a long period of years In this connection it may be mentioned that in the ankle joint skeletal sclerosis and osteophyte formation, as well as genuine ankle joint osteoarthritis, usually appeared decades after the attack of thrombophlebitis of the deep veins of the extremity responsible for the dysfunction of the venous pump of the calf and the high pressure in the intra- and extraosseous veins of the ankle (Arnoldi et al 1972 b)

Synovitis and the developments in juxtaarticular bone (Fig 25)

The synovial membrane seems to react to any abnormal stimulus with essentially the same inflammatory reaction combined with effusion The clinical examples are legion The early synovial reaction is combined with a state of arterial hyperaemia, not only of the synovial membrane but also in juxtaarticular bone, where its effect on bone metabolism becomes visible on the isotope scintigram

In early cases of clinical synovitis the X-rays are usually normal Occasionally, especially in the more severe cases, they show a state of juxtaarticular osteopenia The early stage of synovitis is mainly characterized by increased arterial inflow to the structures of the joint, also in cases that later develop into clinical osteoarthritis This assumption seems to be supported by preliminary results from investigations on artificially induced osteoarthritis on animals (to be published)

The volume increase of synovial membrane and effusion result in increased intraarticular pressure The effect on the synovial membrane is venous stasis and – as long as the arterial inflow is intact – further joint effusion As shown in the experiments on rabbit joints a rise of intraarticular pressure is followed by a rise of intraosseous pressure In the hip joint this must be due to compression of the retinacular veins as they pass from the weight bearing part of the femoral head through the joint

In the proximal part of the femur blockage of the draining vessels leads to intraosseous stasis and hypertension Although the conditions for capillary flow through the femoral head seem to vary e g with physical activity, the findings indicate that the resistance to flow occasionally becomes so great that the oxygen supply to the osteocytes fails The result is bone death

Rest, physical treatment and medication seem to be effective in the treatment of many cases of synovitis Reduction of joint swelling and intraarticular pressure may restore the drainage through the retinacular veins and improve the conditions for bone marrow blood flow The characteristic histological findings of new bone deposited on dead trabeculae could be the result of this improvement of capillary flow

Regional bone necrosis and new bone formation leave the femoral head vulnerable to deformation by mechanical forces

Synovitis and changes in articular cartilage (Fig 25)

Increased permeability of the capillaries of the synovium caused by inflammation, and later by mechanical stasis, results in important changes in the synovial fluid which is the vehicle for the supply of oxygen and nutrition to the articular cartilage The changes noted in Fig 25 are probably just af few of the changes actually taking place However, if the fact holds true that tissue degeneration and death are the end results of a lack of oxygen, this factor alone should be sufficient to explain the fate of cartilage in osteoarthritis Even if there should be some foundation for the opinion held by some authors that the basal layers of cartilage are supplied by the subchondral vessels the circulatory derangement in subchondral bone would embarass this source of supply

We think that the circumstantial evidence supporting our assumption that cartilage degeneration is due to biochemical changes in the synovial fluid is logically impressive We are, however, aware that as far as we know this assumption has not been proved by experimental evidence, although Abdalla & Harrison (1966) found signs of cartilage disorganisation as a result of induced venous stasis and hypertension In our studies of the literature on cartilage research we have noted that, in spite of all the accumulated special knowledge, the ultimate cause of the osteoarthritic changes is generally conceived of as some vague "mechanical dysfunction"

In our opinion mechanical forces are important in the pathomechanism of osteoarthritis, but their main role comes late in the process, when the cartilage is already weakened by tissue degeneration, ultimately due to changes in cellular environment If this course of events is accepted it is easier to explain why idiopathic coxarthrosis is so often unilateral, why the ankle joints are so rarely affected, etc

When the mechanical forces become effective the devitalized cartilage is exposed to the wear and tear that results in complete tissue waste, erosion and denudation of the joint surface The detritus of the worn-down cartilage is caught in the plicae of the synovium and helps to perpetuate the pathological process in this membrane

Other causes of coxarthrosis

We would like to emphasize here that the pathomechanism suggested in this paper and schematically presented in Fig 25 is but one of several pathological processes that may lead to coxarthrosis In this mechanism the key feature is vascular derangement due to high resistance on the venous side of the capillary network but with intact arterial inflow to the structures of the joint

In certain forms of osteoarthritis a local arterial failure plays an important role in the pathomechanism This is the case in coxarthrosis secondary to necrosis of the femoral head after intracapsular fracture of the neck Bone necrosis due to arterial blockage is probably also important for the development of osteoarthritis after transplantation surgery and steroid medication in immunosuppression in certain cases of osteoarthritis in alcoholics, and possibly in other diseases

Correlation of clinical signs and symptoms to the developmental stages of coxarthrosis

In Fig 25 we have made an attempt to correlate the clinical signs and symptoms of coxarthrosis with the various stages of the pathological process While some of these correlations are too obvious to deserve comment a few words on the subject of pain seem necessary

with coxarthrosis secondary to rheumatoid arthritis, Legg Calvé Perthe's disease and trauma, and painful secondary coxarthrosis after these disorders shows the same intraosseous stasis and hyper tension as found in idiopathic coxarthrosis We therefore assume the pathomechanism to be more or less identical in primary and most forms of secondary coxarthrosis Their clinical course may be strikingly different, ranging from the silent period between the congenital hip dislocation and the appearance of clinical osteoarthritis decades later to the rapid development of secondary coxarthrosis after trauma or rheumatoid arthritis These "time factor" differences have probably something to do with the severity of the aetiological factor Apart from the specific effect of the rheumatoid inflammation on, e g the enzyme activity in the joint, patients with rheumatoid arthritis show the lowest synovial oxygen tension measured As mentioned above we believe primary coxarthrosis to be the end result of a series of attacks of synovitis, sometimes stretching over a long period of years In this connection it may be mentioned that in the ankle joint skeletal sclerosis and osteophyte formation, as well as genuine ankle joint osteoarthritis, usually appeared decades after the attack of thrombophle bitis of the deep veins of the extremity responsible for the dysfunction of the venous pump of the calf and the high pressure in the intra- and extraosseous veins of the ankle (Arnoldi et al 1972 b)

Synovitis and the developments in juxtaarticular bone (Fig 25)

Correlation of clinical signs and symptoms to the developmental stages of coxarthrosis

In Fig 25 we have made an attempt to correlate the clinical signs and symptoms of coxarthrosis with the various stages of the pathological process While some of these correlations are too obvious to deserve comment a few words on the subject of pain seem necessary

Patients with coxarthrosis may suffer from different qualities of pain. Most of them complain of pain when the joint is moved, especially when the limits of movements are approached. Pain on loading is equally common. Rest pain is especially typical of coxarthrosis. It is characteristic for the pain in coxarthrosis that it tends to radiate down the thigh to the knee region.

Cartilage does not contain nerves, but sensitive nerve endings are found in the synovium and the fibrous capsule as well as in the bone marrow, where the nerves are found together with the blood vessels. Recently, Reimann & Christensen (1977) demonstrated a higher density of nerves in osteoarthritic subchondral bone marrow than in normal and ascribed the increase to the hypervascularity of osteoarthritis.

Joint distension by effusion may in itself be painful and the pain increases when the swollen joint is moved. Stretching of the capsule and pinching of swollen synovium are obvious causes of pain. However, the reaction of intraosseous pressure to rise in intraarticular pressure brings another pain mechanism into focus. By now most authors agree that rest pain is due to intraosseous stasis and hypertension (Arnoldi et al. 1971, Bulstrode 1976). The threshold for pain seems to vary individually (Lemperg & Arnoldi 1978), but in most cases a rise above 40 mmHg will produce the characteristic rest pain.

In a joint with effusion, forced movements raise the pressure in the joint and may increase the intraosseous pressure above the threshold of pain.

The intraosseous phlebograms showed dilation of all veins in the bone marrow of patients with painful coxarthrosis and the intraosseous engorgement pain syndrome. Distension of veins is known to be connected with the "bursting pain" characteristic of patients with chronic venous insufficiency of the lower leg or idiopathic dysfunction of the venous pump of the calf (cruralgia orthostatica) (Arnoldi 1964 and 1976). Thus, there are some indications that the distension of the veins caused by intraosseous venous stasis may be the factor responsible for the rest pain of osteoarthritis. The findings that venous dilation and increased intraosseous pressure can be demonstrated not only in the femoral head and neck, but also – although less pronounced – throughout the bone marrow of the femur, might explain the pain radiating towards the knee joint characteristic of coxarthrosis.

Future problems

In our opinion the results of the investigations presented in this paper give a reasonable basis for most of the developments sketched in Fig. 25. The changes represent disturbances of an interacting mechanism and we have attached importance to the internal correlation of our findings. At the time of writing our main problem – still poorly supported by experimental evidence – is the effect of changes in the composition of the synovial fluid upon articular cartilage. However, our choice of investigations has been determined by the resources of our laboratories and are not a result of any bias.

One good reason for publishing the paper now is that it might provoke critical inquiry in centres with greater resources in the field of cartilage research.

Patients with coxarthrosis may suffer from different qualities of pain Most of them complain of pain when the joint is moved, especially when the limits of movements are approached Pain on loading is equally common Rest pain is especially typical of coxarthrosis It is characteristic for the pain in coxarthrosis that it tends to radiate down the thigh to the knee region

Cartilage does not contain nerves, but sensitive nerve endings are found in the synovium and the fibrous capsule as well as in the bone marrow, where the nerves are found together with the blood vessels Recently, Reimann & Christensen (1977) demonstrated a higher density of nerves in osteoarthritic subchondral bone marrow than in normal and ascribed the increase to the hyper vascularity of osteoarthritis

Joint distension by effusion may in itself be painful and the pain increases when the swollen joint is moved Stretching of the capsule and pinching of swollen synovium are obvious causes of pain However, the reaction of intraosseous pressure to rise in intraarticular pressure brings another pain mechanism into focus By now most authors agree that rest pain is due to intraosseous stasis and hypertension (Arnoldi et al 1971, Bulstrode 1976) The threshold for pain seems to vary individually (Lemperg & Arnoldi 1978), but in most cases a rise above 40 mmHg will produce the characteristic rest pain

In a joint with effusion, forced movements raise the pressure in the joint and may increase the intraosseous pressure above the threshold of pain

The intraosseous phlebograms showed dilation of all veins in the bone marrow of patients with painful coxarthrosis and the intraosseous engorgement pain syndrome Distension of veins is known to be connected with the "bursting pain" characteristic of patients with chronic venous insufficiency of the lower leg or idiopathic dysfunction of the venous pump of the calf (cruralgia orthostatica) (Arnoldi 1964 and 1976) Thus, there are some indications that the distension of the veins caused by intraosseous venous stasis may be the factor responsible for the rest pain of osteoarthritis The findings that venous dilation and increased intraosseous pressure can be demonstrated not only in the femoral head and neck, but also – although less pronounced – throughout the bone marrow of the femur, might explain the pain radiating towards the knee joint characteristic of coxarthrosis

Future problems

In our opinion the results of the investigations presented in this paper give a reasonable basis for most of the developments sketched in Fig 25 The changes represent disturbances of an interacting mechanism and we have attached importance to the internal correlation of our findings At the time of writing our main problem – still poorly supported by experimental evidence – is the effect of changes in the composition of the synovial fluid upon articular cartilage However our choice of investigations has been determined by the resources of our laboratories and are not a result of any bias

One good reason for publishing the paper now is that it might provoke critical inquiry in centres with greater resources in the field of cartilage research

KNEE ARTHROPLASTY IN RHEUMATOID APTHRITIS

An analysis of 240 cases of hemi-, hinge and resurfacing arthroplasties

1. INTRODUCTION

While arthroplasty of the knee was attempted already 100 years ago, the techniques used today are based on the pioneer work in the 1950s (McIntosh 1967, Shiers 1954, Walldius 1957 and McKeever 1959). During the 1970s the development and use of new designs for knee arthroplasty have developed exponentially, at present more than 400 different designs are available on the market, and in Sweden 1 000 arthroplasties are performed yearly. It is not easy for the surgeon to choose between widely different concepts and methods for arthroplasty of the knee published results are confusing, contradictory and difficult to interpret. An important reason for this confusion is that most published series fail to make a distinction between osteoarthrosis and rheumatoid arthritis. However, most patients subjected to arthroplasty of the knee because of arthrosis do not suffer from generalized arthropathy and the knee condition is focal (Ahlbäck 1968), whereas rheumatoids have a generalized disease, characterized by poly-arthropathy with panarthritis The aim of this work was to compare the clinical results and identify complications and reasons for failures of three different arthroplasty methods using the hemi-, hinge and resurfacing principles All patients had rheumatoid arthritis (RA) (Golding 1966) and population differences in the three materials were identified.

SURGERY FOR RHEUMATOID ARTHRITIS OF THE KNEE IN LUND

From 1967 through 1976, more than 1 000 operations were performed for rheumatoid arthritis of the knee at the Department of Orthopaedic Surgery at the University Hospital of Lund, Sweden. Synovectomy was by far the most common operation (542 cases). For correction of deformities high tibial osteotomies were performed in 75 knees and capsulotomies in 60. Baker cysts were excised in 53 knees Up to 1973, 27 arthrodeses were carried out (Brattström 1971)

This work analyses the result of 240 consecutive knee arthroplasties in rheumatoid arthritis performed in Lund 1967-1976 The material includes 67 McIntosh arthroplasties with observation time on an average 3.3 years (1.0-6 0) operated 1967-1972, 64

II. MATERIAL AND METHODS

All patients were admitted to the Department of Orthopaedic Surgery or Rheumatology at the University Hospital of Lund, and operated at the Department of Orthopaedics. The diagnosis of rheumatoid arthritis was established according to the American Rheumatoid Association's (ARA) criteria for classical, definite and probable RA (Golding 1966), and will henceforth be termed RA.

Preoperative status

Case records and patient interviews provided information about previous disease, the preoperative ARA functional classification (Berglund et al 1973) and social status. Preoperative degree of pain and dependence on walking or other aids were part of the status at admission recorded by the surgeon and the physiotherapist.

This status included observations of exudate and capsular thickening, femoro-patellar crepitation and decreased lateral mobility of the patella. Sagittal instability was noted by the anterior drawer sign with the knee flexed 90°. Lateral instability was measured with the knee flexed 5° (Hallén 1965). Range of movement of the knee was measured with a goniometer. Unless otherwise indicated extension was always passive. Varus and valgus was measured in the standing position using a goniometer, an FT-angle of 174° was defined as neutral (Fig 2). The quadriceps power was measured as a breaking force on isometric contraction with 90° knee flexion and resistance applied immediately proximal to the talo-crural joint.

Complications

Early complications during the operation and postoperatively within two months as well as late complications were identified from the case records and interviews

Status at follow-up

The author examined all patients. Parameters were identical to what was described under preoperative objective status. ESR was registered at follow-up for estimating disease activity.

EVALUATION SYSTEM

The Marmor? Insall? [illegible] (1969) knee joint evaluation system was used throughout. A good result is

Guépar arthroplasties with observation time on an average 2.7 years (1.1-4.3) operated 1972-1976 and 109 Marmor arthroplasties with observation time on an average 2.2 years (1.0-3.6) operated 1974-1976.
These three arthroplasties represent three different replacement principles.

The McIntosh prosthesis is a hemiprosthesis which resurfaces the tibial condyle and by a spacer effect can correct deformity and instability. From 1967 through 1970, the McIntosh prosthesis was the only arthroplasty used in Lund and the indications were therefore quite liberal. Attrition of the femoral condyles to a slight degree was not a contraindication. Lateral instability and malposition in varus-valgus up to 30° were also accepted.

The Guépar prosthesis is a simple mechanical hinge cemented in the medullary cavity. The prosthesis has a fixed transverse axis of rotation, and stability is totally independent of the soft tissue of the knee: constrained principle. From 1972 through 1973, the Guépar hinge prosthesis was that most used at the clinic. This was partly due to the existence of a pool of patients where an arthrodesis had been the only realistic alternative because the McIntosh prosthesis was insufficient. Since 1974, the use of the Guépar prosthesis was substantially reduced following the introduction of the Marmor prosthesis.

The Marmor prosthesis resurfaces the femur and the tibia and is thus a total prosthesis for the femoro-tibial (FT)-joints, having the same propensity as the McIntosh prosthesis to correct deformity and instability. From 1974, this prosthesis totally replaced the McIntosh prosthesis and during 1975 and 1976, partly even the indication for using a Guépar prosthesis. It was also used in younger patients.

The McIntosh and Marmor prostheses do not decrease free movements between the femur and tibia and stability in the arthroplasty depends entirely on the ligaments and extra-articular soft tissue: unconstrained principle.

By the end of the period dealt with in this work, the Guépar prosthesis had been largely replaced by the Attenborough prosthesis, which represents the group of hemiconstrained prostheses that permit rotation between the tibia and the femur and a certain limited lateral instability.

II. MATERIAL AND METHODS

All patients were admitted to the Department of Orthopaedic Surgery or Rheumatology at the University Hospital of Lund, and operated at the Department of Orthopaedics. The diagnosis of rheumatoid arthritis was established according to the American Rheumatoid Association's (ARA) criteria for classical, definite and probable RA (Golding 1966), and will henceforth be termed RA.

Preoperative status

Case records and patient interviews provided information about previous disease, the preoperative ARA functional classification (Berglund et al. 1973) and social status. Preoperative degree of pain and dependence on walking or other aids were part of the status at admission recorded by the surgeon and the physiotherapist.

This status included observations of exudate and capsular thickening, femoro-patellar crepitation and decreased lateral mobility of the patella. Sagittal instability was noted by the anterior drawer sign with the knee flexed 90°. Lateral instability was measured with the knee flexed 5° (Hallén 1965). Range of movement of the knee was measured with a goniometer. Unless otherwise indicated extension was always passive. Varus and valgus was measured in the standing position using a goniometer, an FT-angle of 174° was defined as neutral (Fig 2). The quadriceps power was measured as a breaking force on isometric contraction with 90° knee flexion and resistance applied immediately proximal to the talo-crural joint.

Complications

Early complications during the operation and postoperatively within two months as well as late complications were identified from the case records and interviews

Status at follow-up

The author examined all patients. Parameters were identical to what was described under preoperative objective status. ESR was registered at follow-up for estimating disease activity

EVALUATION SYSTEM

The Wernfeld's (1969) knee joint evaluation system was used throughout. A good result is

equal to a low score (minimum 0, maximum 33 demerit points). Points are given for each of the parameters: pain, use of walking aids, flexion, extension defect, varus or valgus deformity at weight-bearing, lateral instability and quadriceps weakness (Table I). The total is thus an expression of the deviation from normal. The same value of points can however represent different combinations of pathologic findings. The points allocated for a given parameter are chosen with regard to the functional consequences. A total score between 0 and 2 is described as excellent, between 3 and 6 as good, between 7 and 10 as fair and 11 or more as poor. On statistical analysis of the material the group with 0 to 6 points is called "satisfactory" and 7 or higher "not satisfactory".

In using Weinfeld's point system it is important to bear in mind that the score for the specific knee reflects the deviation from a normal knee (0 point) and a knee that at follow-up has a score of 7 or more, thus being placed in the group "not satisfactory", can be judged by both the surgeon and the patient as being improved. The patient can, for instance, preoperatively score 14 points and at follow-up 7 points; in spite of this improvement the case would still fall into the "not satisfactory" group.

Weinfeld's evaluation system was chosen because it is largely based on objective criteria and is numerical in nature. Thus the risk of biased judgement arising from the patient's and the examiner's loyalty to the surgeons is reduced. It facilitates comparison between pre- and postoperative status and comparison of results according to different replacement methods. The system is well suited for data computing and statistical analysis. A number of other evaluation systems exist and this makes comparison between different works extremely difficult (Andersson 1972). The Weinfeld's system has been used by Potter (1972) and Jani and Morscher (1973) for evaluation of arthroplasty with the McIntosh prosthesis.

Table 1.
Weinfeld's evaluation system

	Points
Pain	
None or unimportant	0
After more than 200 m walking	1
After less than 200 m walking	3
Immediately at weight-bearing	6

	Good	3–6 points	
	Fair	7–10 points	7–33 points "Not satisfactory"
	Poor	11–33 points	

equal to a low score (minimum 0, maximum 33 demerit points) Points are given for each of the parameters pain, use of walking aids, flexion, extens on defect, varus or valgus deformity at weight-bearing, lateral instability and quadriceps weakness (Table I) The *total is thus an expression of the deviation from normal The same value of points can* however represent different combinations of pathologic findings The points allocated for a given parameter are chosen with regard to the functional consequences A total score between 0 and 2 is described as excellent, between 3 and 6 as good, between 7 *and 10 as fair and 11 or more as poor. On statistical analysis of the material the group* with 0 to 6 points is called satisfactory and 7 or higher not satisfactory

In using Weinfeld s point system it is important to bear in mind that the score for the *specific knee reflects the deviation from a normal knee (0 point) and a knee that at* follow-up has a score of 7 or more, thus being placed in the group not satisfactory , can be judged by both the surgeon and the patient as being improved. The patient can, for instance, preoperatively score 14 points and at follow-up 7 points in spite of this improvement the case would still fall into the not satisfactory group.

Weinfeld s evaluation system was chosen because it is largely based on objective criteria and is numerical n nature. Thus the risk of biased judgement arising from the patient s and the examiner s loyalty to the surgeons is reduced It facilitates comparison between pre- and postoperative status and compar son of results accord ng to d fferent replacement methods The system is well suited for data computing and statistical analysis. A number of other evaluation systems exist and this makes comparison between different works extremely difficult (Andersson 1972). The Weinfeld s system has been used by Potter (1972) and Jani and Morscher (1973) for evaluation of arthroplasty with the McIntosh prosthesis

Fig 1b Obliteration of the articular space in the lateral compartment.

Fig. 1c. Attr tion of moderate degree in the med al compartment

Fig 1d Attrit on of severe degree in the med al compartment.

Subjective status at follow-up

Pain at rest or at weight-bearing was recorded, the latter in relation to walking distance. Use of support at walking was recorded. Details regarding medication during the observation period were noted Based on information concerning activities of daily living (ADL-status) and need for public assistance, the ARA functional classification was determined and the socio-economic status assessed Pain at weight-bearing, arthroplasties and arthrodeses performed in other major joints in the lower extremities were also registered. The patients were asked for their opinion of the result of the operation

ROENTGEN MATERIAL

The analysis was based on the following roentgen examinations.
Preoperatively. Standard frontal and lateral projections of the knee and an axial projection of the femoro-patellar joints (FP-joints) in 30° of knee flexion were usually taken in the supine position, and frontal projections on weight-bearing in varus and valgus provocation according to Norman (Hagstedt 1974). Because of pain, synovitis, flexion contracture and varus and valgus malposition, extreme provocation was not always possible.
At follow-up. Similar examinations as preoperatively, axial projection of FP-joint only when clinically indicated For comparison of position of prosthetic components the immediate postoperative and the follow-up roentgen examinations were compared.

Analysis of roentgen material

The author evaluated the roentgen material of the McIntosh and Guépar material The Marmor material was evaluated in co-operation with the Roentgenological Department II at the University Hospital of Lund (Niels Egund and Hildur Laurusdottir) Clinical and roentgenological observations were not correlated until all observations were registered and data analysed

Cartilage reduction and attrition in FT-joint preoperatively. Analysis of the medial and lateral compartments were made on frontal projections of the knee in weight-bearing and varus provocation and valgus provocation, respectively

A simplified model of Ahlbäck s (1968) classification for gonarthrosis was used The simplification was adopted for the following reasons.
1) RA as opposed to osteoarthrosis usually involves both FT-compartments. In this work the destruction in the most pathological compartment was selected for classification.
2) Destruction in RA does not develop uniformly, through cyst formation and subchondral fractures bone attrition can be simulated even if total cartilage destruction is not present

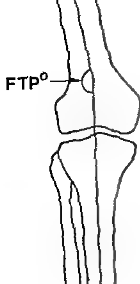

Fig. 2. The FTP-angle was defined as the lateral open angle between the longitudinal axes of femur and tib ■ in the frontal exposure on we ght-bearing and provocation in varus and valgus (Hagstedt 1974).

Analys s of roentgen mater al at follow-up

McIntosh

Destruction of the femoral condyles was judged on the bas s of provoked frontal exposures at weight-bearing and a standard lateral exposure The FTP angle was assessed using the same methods as in the preoperative examination The position of the prosthesis was assessed on the bas s of standard projections on frontal and lateral views Comparison was made with the mmediate postoperative exam nation

Guépar

Position of prosthesis, cement surround ng the stems and presence of operative fractures were registered on the standard project ons in lateral and frontal views The maximum width of the rad olucent zones around the bone cement in the presence of infection and/or fracture were reg stered in all roentgen exposures during the observation time In the rest of the mater al, the width of the zone was reg stered one year after operation. Scalloping and periosteal reactions were looked for in all exam nations

Marmor

FTP angle measurement was made on the same bas s as at the preoperative exam nation Based on standard frontal and lateral projections, the angle of the t bial components in relation to the longitud nal axes of tib a was measured Fracture or buckling of the indicator wire was noted as a sign of loosening of the prosthes s The rad olucent zone under the t b al component was measured at the last exam nat on By comparing the first postoperative examinat on and the examinat on at follow-up, changes in the position of prosthet c components were noted The position of the femoral component in relation to the tib al plates was assessed

Classification of cartilage reduction and attrition in FT-joints preoperatively (Hagstedt 1974)

Narrowing of the articular space was defined as total cartilage thickness of 1-3 mm in the most destroyed compartment (equal to Ahlbäck class I). (Fig. 1a).

Obliteration of the articular space was defined as cartilage thickness of less than 1 mm in the most destroyed compartment, but no certain destruction of subchondral bone (equal to Ahlbäck class II). (Fig. 1b).

Attrition of bone was defined as changed configuration of the condyle of the tibia and/or femur. This class also included knees with subluxation of the tibia (equal to Ahlbäck classes III-V). (Fig. 1c-1d).

Classification of cartilage reduction and attrition in FP-joints

Normal cartilage was defined as at least 3 mm cartilage thickness and well-marked FP-joint spaces.

Cartilage reduction was defined as cartilage thickness of 0-3 mm and well-marked FP-joint spaces.

Attrition was defined as not detectable or a pathological configuration of the joint line. This group included cases with lateralization or medialization of the patella.

Measurements of varus and valgus deviations

The longitudinal axes of the femur and tibia were marked on the frontal projections with varus-valgus provocation. The lateral open angle between the longitudinal axes of the femur and tibia at weight-bearing was designated the FTP-angle (Femoro-tibial angle Provoked) (Fig. 2). The FTP-angle was measured on varus and valgus provocation and the largest divergence from 174° was recorded.
Hagstedt in a study of gonarthrosis indicated the normal variation for the FT-angle at 168-180°. The difference between FTP-angle in varus and valgus provocation was calculated as a measurement of instability in the knee at weight-bearing.
In the Marmor and Guépar material lateral subluxation of tibia was also registered when found to exceed 5 mm.

The errors in angle registration were considerable because short films were used in part of the examinations and presence of flexion contractures.

Fig. 2. The FTP-angle was defined as the lateral open angle between the longitudinal axes of femur and tibia in the frontal exposure on weight-bearing and provocation in varus and valgus (Hagstedt 1974).

Analysis of roentgen material at follow-up

McIntosh

Destruction of the femoral condyles was judged on the basis of provoked frontal exposures at weight-bearing and a standard lateral exposure. The FTP angle was assessed using the same methods as in the preoperative examination. The position of the prosthesis was assessed on the basis of standard projections on frontal and lateral views. Comparison was made with the immediate postoperative examination.

Guépar

Position of prosthesis, cement surrounding the stems and presence of operative fractures were registered on the standard projections in lateral and frontal views. The maximum width of the radiolucent zones around the bone cement in the presence of infection and/or fracture were registered in all roentgen exposures during the observation time. In the rest of the material, the width of the zone was registered one year after operation. Scallop ng and periosteal reactions were looked for in all examinations.

Marmor

FTP angle measurement was made on the same basis as at the preoperative examination. Based on standard frontal and lateral projections, the angle of the tibial components in relation to the longitudinal axes of tibia was measured Fracture or buckling of the indicator wire was noted as a sign of loosening of the prosthesis. The radiolucent zone under the tibial component was measured at the last examination. By comparing the first postoperative exam nation and the examination at follow-up, changes in the position of prosthet c components were noted. The position of the femoral component in relation to the tib al plates was assessed

Classification of cartilage reduction and attrition in FT-joints preoperatively (Hagstedt 1974)

Narrowing of the articular space was defined as total cartilage thickness of 1-3 mm in the most destroyed compartment (equal to Ahlbäck class I). (Fig. 1a).

Obliteration of the articular space was defined as cartilage thickness of less than 1 mm in the most destroyed compartment, but no certain destruction of subchondral bone (equal to Ahlbäck class II). (Fig. 1b).

Attrition of bone was defined as changed configuration of the condyle of the tibia and/or femur. This class also included knees with subluxation of the tibia (equal to Ahlbäck classes III-V). (Fig. 1c-1d).

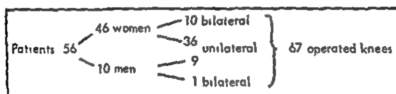
Classification of cartilage reduction and attrition in FP-joints

Normal cartilage was defined as at least 3 mm cartilage thickness and well-marked FP-joint spaces.

Cartilage reduction was defined as cartilage thickness of 0-3 mm and well-marked FP-joint spaces.

Attrition was defined as not detectable or a pathological configuration of the joint line. This group included cases with lateralization or medialization of the patella.

Measurements of varus and valgus deviations



The longitudinal axes of the femur and tibia were marked on the frontal projections with varus-valgus provocation. The lateral open angle between the longitudinal axes of the femur and tibia at weight-bearing was designated the FTP-angle (Femoro-tibial angle Provoked) (Fig. 2). The FTP-angle was measured on varus and valgus provocation and the largest divergence from 174° was recorded.
Hagstedt in a study of gonarthrosis indicated the normal variation for the FT-angle at 168-180°. The difference between FTP-angle in varus and valgus provocation was calculated as a measurement of instability in the knee at weight-bearing.
In the Marmor and Guépar material lateral subluxation of tibia was also registered when found to exceed 5 mm.

The errors in angle registration were considerable because short films were used in part of the examinations and presence of flexion contractures.

MATERIAL AND METHODS

From 1967 through 1973 the McIntosh prosthesis was used in 59 patients for a total of 70 knees. A follow-up was carried out during 1973–1974, two patients were examined in 1976. Three patients (3 knees) were excluded from the material one patient could not be traced, two patients died from unrelated causes more than a year following surgery but prior to the follow-up. According to case records, the result were acceptable to the three patients. The follow-up thus included 56 patients with 67 operated knees (Fig. 3). The average age at operation was 54 years (26–74).

Fig. 3

The observation time was on an average 3.3 years (1.0–6.0 years). Six patients had at follow-up been re-operated with another type of prosthesis (one bilateral). In these knees, the observation time was calculated up to the time for re-operation

In more than half of the operated knees, RA had been present for more than 10 years preoperatively No patients with less than 2 years of RA were operated upon.

Table 2.
ESR preoperatively

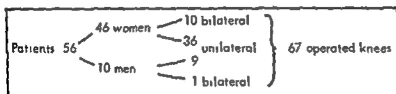
ESR mm/H	0-25	25-65	66-150	Insufficient data
Knees	21	32	13	1

Previous treatment of the operated knee

Intra-articular cortisone. In 28 knees, between 1 and 10 cortisone injections were given and in 27 knees, more than 10 injections Only 12 knees were never treated with intra-ticular cortisone

Statistical methods [x]

Common parametric tests generally make certain assumptions about the population being tested and further assume at least interval level of measurement. From a statistical point of view the important variables in this clinical investigation must be considered at not ordinal level of measurements and for that reason tests concerning association between variables, proportions and differences in location were accomplished by means of the following nonparametric procedures X^2-test, McNemar test, Wilcoxon Signed-Rank test and Kruskal-Wallis one-way test. In applicable cases distribution-free multiple comparison techniques were used in judging treatments with a controlled level of significance (experimentwise error rate).



All processing of the data material was carried out by standard statistical software at the computer center of the University of Lund, in certain situations by means of specially developed programs for a minicomputer.

[x] Aid in the statistical analysis is gratefully acknowledged to Mr. Lars Ek.

MATERIAL AND METHODS

From 1967 through 1973 the McIntosh prosthesis was used in 59 patients for a total of 70 knees. A follow-up was carried out during 1973–1974, two patients were examined in 1976. Three patients (3 knees) were excluded from the material one patient could not be traced, two patients died from unrelated causes more than a year following surgery but prior to the follow-up. According to case records, the result were acceptable to the three patients. The follow-up thus included 56 patients with 67 operated knees (Fig. 3). The average age at operation was 54 years (26-74).

Fig. 3

The observation time was on an average 3,3 years (1,0-6,0 years). Six patients had at follow-up been re-operated with another type of prosthesis (one bilateral). In these knees, the observation time was calculated up to the time for re-operation.

In more than half of the operated knees, RA had been present for more than 10 years preoperatively No patients with less than 2 years of RA were operated upon.

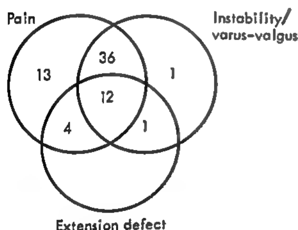
Table 2.
ESR preoperatively.

ESR mm/h	0-25	25-65	66-150	Insufficient data
Knees	21	32	13	1

Previous treatment of the operated knee

Intra-articular cort sone. In 28 knees, between 1 and 10 cortisone injections were given and in 27 knees, more than 10 injections. Only 12 knees were never treated with intra-articular cortisone

Synovectomy. Chemical synovectomy, using osmium acid, had been carried out in seven knees and a combination of chemical and surgical synovectomy in 22. Surgical synovectomy alone had been made in eight knees making a total of 37 chemical and/or surgical synovectomies, 25 of them between one and three years before arthroplasty.



Capsulotomy was performed in six knees for correction of a flexion contracture.

High tibial osteotomy was carried out in four knees to correct a valgus deformity.

Indications for arthroplasty

The indications for the McIntosh arthroplasty were not uniform. During the latter part of the period, the indications were more restricted as a consequence of increasing experience and introduction of new prosthetic alternatives. The Venn-diagram (Fig. 4) shows the clinical symptoms that motivated the operation.

Fig. 4.
Clinical indication for McIntosh arthroplasty in 67 knees.

Pain at weight-bearing or on walking less than 200 m.
Instability $\geqq 10^\circ$ and/or
Varus
Valgus $\geqq 10^\circ$
Extension defect $>15^\circ$

Pain was found in all except two knees, operated because of instability and extreme valgus. In 48 knees a combination of pain and considerable deformity and/or instability was found and 16 had pain and an extension defect. Decreased flexion was not of such degree as to constitute an indication for arthroplasty.

Contraindications. With an extension defect of more than 30°, varus or valgus of more than 30° and subluxation of the tibia of more than 1 cm, it was not considered technically possible to construct a mobile yet stable and painfree joint by means of a McIntosh arthroplasty. In these knees, arthrodesis was considered or the development of a better prosthesis was awaited.

Operative technique

Two surgeons have operated on 64 knees and assisted at ■ further three.(Fig. 5a-b). The operation was performed under general or epidural anaesthesia through a medial parapatellar incision in ■ bloodless field. In 20 cases during the first years, the tibial tuberosity was detached to allow an easier approach to the knee joint In the remaining 47 knees the patella was dislocated laterally. A synovectomy was performed In the presence of ■ flexion contracture a wedge was chiselled away from the tibia so that full extension became possible. An adequately sized prosthesis was chosen to allow for circumferential cortical bearing and lateral stability

Bone cement as recommended by Kates (Brattström 1973) was used during 1971-1972 in 25 knees for attaching the prosthesis.

Unicompartment arthroplasty was performed in 14 knees (Fig 6a-b), 11 of those in the lateral compartment. If the tibial tuberosity was detached, it was reattached with ■ screw or staple and ■ long leg plaster cast with an opening for the patella was applied following which the bloodless field was released Vacuum drainage was maintained for 24-48 hours postoperatively. Prophylactic antibiotics and anticoagulation therapy were not used routinely

Postoperative treatment

During the first postoperative days quadriceps exercise was started and the patella was passively mobil zed From the third day passive flexion and extension was started. From the tenth day, the patient was allowed to flex and extend actively and to walk with crutches After two weeks full weight-bearing was permitted and if flexion d d not reach 90° four weeks after operation, manipulation under anaesthesia was carried out. If the tibial tuberosity was detached and reattached the patient was treated in the long leg plaster cast for two weeks, and during the next four weeks increasing passive flexion and weight-bearing with the use of a dorsal plaster slab was permitted If passive flexion did not reach 60° after three weeks, open mob lization was performed. This was carried out in 15 of 20 operations where the tibial tuberosity was detached and reattached.

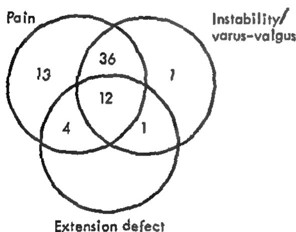
COMPLICATIONS

Operative complications and technical difficulties

In 25 of 67 operations, technical difficulties or complications were encountered and modifications were adopted.

Fracture of the tibia In one knee, the cortical bone in the t b al condyle was fractured

Synovectomy. Chemical synovectomy, using osmium acid, had been carried out in seven knees and a combination of chemical and surgical synovectomy in 22. Surgical synovectomy alone had been made in eight knees making a total of 37 chemical and/or surgical synovectomies, 25 of them between one and three years before arthroplasty.



Capsulotomy was performed in six knees for correction of a flexion contracture.

High tibial osteotomy was carried out in four knees to correct a valgus deformity.

Indications for arthroplasty

The indications for the McIntosh arthroplasty were not uniform. During the latter part of the period, the indications were more restricted as a consequence of increasing experience and introduction of new prosthetic alternatives. The Venn-diagram (Fig. 4) shows the clinical symptoms that motivated the operation.

Fig. 4.
Clinical indication for McIntosh arthroplasty in 67 knees.

Pain at weight-bearing or on walking less than 200 m.
Instability ≧ 10° and/or
Varus ≧10°
Valgus
Extension defect >15°

Pain was found in all except two knees, operated because of instability and extreme valgus. In 48 knees a combination of pain and considerable deformity and/or instability was found and 16 had pain and an extension defect. Decreased flexion was not of such degree as to constitute an indication for arthroplasty.

Contraindications. With an extension defect of more than 30°, varus or valgus of more than 30° and subluxation of the tibia of more than 1 cm, it was not considered technically possible to construct a mobile yet stable and painfree joint by means of a McIntosh arthroplasty. In these knees, arthrodesis was considere
prosthesis was awaited.

Dislocation of the prosthesis. During manipulation under anaesthesia both plates were pressed down into the tibial condyles and a horizontal rotation of one of the plates occurred which resulted in a passive extension defect of 20°.

Miscellaneous In one knee there was pain at weight-bearing Exploration of the knee revealed a fragment of cement posterior to the lateral prosthesis This was removed with relief of pain Another knee with pain on weight-bearing was explored and a number of subchondral cysts in the lateral femoral condyle were cleared of synovial membrane. The cavity was filled with bone cement with relief of pain.

Hospital stay The average duration was 48 days (18-126). In those patients where the tibial tuberosity had been detached, the length of stay was increased by about half as much aga n.

Late complications

Late complications occurred in eight knees.

Patella dislocation. In one knee the patella dislocated as a result of extreme valgus caused by compression of the lateral femoral condyle and a 2 cm lateralization of the tibia (Fig 9). A hinge prosthesis was subsequently inserted in this knee.

Dislocation of the prosthesis. In one knee, a progressive sinking in of the lateral prosthesis and a lateralization of the t bia developed In one knee the lateral plate dislocated and at revision the plate was fixed with cement. At a later date the medial plate dislocated to the lateral compartment (Fig. 11) and a hinge prosthesis was eventually inserted.

Collapse of the condyles. Two knees developed an increasing collapse of the lateral femoral condyle This resulted in increasing valgus and instability. In both knees, a h gh tibial osteotomy was carried out. In one knee following a prosthesis in the lateral compartment, an increas ng collapse of the med al tibial condyle developed which led to a prosthesis being inserted in the medial compartment as well.

Fractures. One patient who was operated bilaterally in 1971 sustained a supracondylar fracture of the left femur without adequate trauma followed 12 months later by an ident cal fracture in the r ght femur (stress fractures). Both fractures healed uneventfully.

when chiselling A fracture of the intercondylar eminence with a dislocation of the sertion of the anterior cruciate ligament was noted in seven knees. Five of the fract were left untreated. In one the eminence was reattached with a wire and in one wit screw. The screw perforated the posterior cortex of the tibia and because of the risk erosion of the popliteal artery the screw was removed three weeks later.

Cysts in the tibia In seven knees one of the tibial condyles was eroded by a subchor cyst and extensive resection was necessary to achieve satisfactory bone support unde prosthesis, in three cases the cyst was filled with bone cement

Wrong size of prosthesis In three operations the thickest prosthesis was not adequate compensate for the amount of destruction in the lateral condyle In one, the biggest plate was not large enough to obtain cortical bearing along the entire circumference in another a prosthesis that was too thin was used as the correct size was not availabl

Patella dislocation In one knee with 10° of valgus preoperatively, the patella was f to be dislocated at operation and despite a medial transfer of the tibial tuberosity an medial plication of the joint capsule, it remained dislocated

Extension defect. In two knees full correction of an extension defect was not achieve and a 10° lag had to be accepted. In one of these knees this was still present at the follow-up.

Incongruity. In one knee the arthroplasty was complicated by a lateral subluxation of tibia and in another congruity between the femoral condyles and the prostheses was nc obtained.

Postoperative complications

Complications occurred in e ght knees. No thrombosis or embolism occurred in this series. No patient died as a direct result of the operation.

Complicated wound healing - superficial infection. In four knees the wound failed to heal within four weeks. In two a culture was negative and no ant biotics were given. I the other two, the culture was positive (plasma coagulating staphylococcus, entero-coccus and staph. aureus) and antibiotics were used. In these knees, the wounds heale later without signs of deep infection

Dislocation of the patella In one knee there was crepitation at the FP-jo nt and pain at extension Clinically the patella was found subluxated laterally in the last 30° of extension.

Dislocation of the prosthesis. During manipulation under anaesthesia both plates were pressed down into the tibial condyles and a horizontal rotation of one of the plates occurred which resulted in a passive extension defect of 20°

Miscellaneous In one knee there was pain at weight-bearing. Exploration of the knee revealed a fragment of cement posterior to the lateral prosthesis. This was removed with relief of pain. Another knee with pain on weight-bearing was explored and a number of subchondral cysts in the lateral femoral condyle were cleared of synovial membrane. The cavity was filled with bone cement with relief of pain.

Hospital stay The average duration was 48 days (18-126). In those patients where the tibial tuberosity had been detached, the length of stay was increased by about half as much again.

Late complications

Late complications occurred in eight knees.

Patella dislocation In one knee the patella dislocated as a result of extreme valgus caused by compression of the lateral femoral condyle and a 2 cm lateralization of the tibia (Fig. 9). A hinge prosthesis was subsequently inserted in this knee.

Dislocation of the prosthesis. In one knee, a progressive sinking in of the lateral prosthesis and a lateralization of the tibia developed. In one knee the lateral plate dislocated and at revision the plate was fixed with cement. At a later date the medial plate dislocated to the lateral compartment (Fig. 11) and a hinge prosthesis was eventually inserted.

Collapse of the condyles. Two knees developed an increasing collapse of the lateral femoral condyle. This resulted in increasing valgus and instability. In both knees, a high tibial osteotomy was carried out. In one knee following a prosthesis in the lateral compartment, an increasing collapse of the medial tibial condyle developed which led to a prosthesis being inserted in the medial compartment as well.

Fractures. One patient who was operated bilaterally in 1971 sustained a supracondylar fracture of the left femur without adequate trauma followed 12 months later by an identical fracture in the right femur (stress fractures). Both fractures healed uneventfully.

FOLLOW-UP EVALUATION

The seven parameters in Weinfeld's evaluation system (see page 9) formed the basis for evaluation of status preoperatively and at follow-up. In the diagrams, the status at follow-up is marked by the position on the X-axes and the status preoperatively by the position on the Y-axes. Positions along the oblique line indicate unchanged status, over the oblique line improved and below the oblique line worse.

Table 3.
Pain.

	Follow-up 14	13	12	22	6	Sum

6	4	4	3	9	2	22	
3	3	1	2	1		7	Preop.
1			1			1	
0	1					1	
Points	0	1	3	6	7		

For the patient, pain was the primary indication for operation. In 47 knees pain was less severe at follow-up than preoperatively, unchanged in 16 and more severe in four.

In 40 of the operated knees pain on walking less than 200 m was *present at follow-up*, a synovial swelling was found in seven of those. Quadriceps power less than 100N was found in 32 and no less than 28 of them had pain when walking less than 200 m, the correlation was significant (Chi^2 p 0 0003)

Table 4.
Use of support at walking

	Follow-up 12	21	9	25	Sum

4	2	2	1	5
2	22	13	3	38
0	13	5		18
Points (column sums)	37	20	4	

In 43 knees with preoperative lateral instability an improvement was achieved in 26 knees The instab lity was unchanged in 27 and increased in eight.

Fig 7
Varus-valgus deform ty at weight-bearing (clinical)

Follow-up

Preoperatively

Preoperatively seven knees were in more than 10° of varus and 30 were in more than 10° of valgus At follow-up four knees were in varus, in only one of them was the deformity present preoperatively In 16 knees 10-20° of valgus was found at follow-up and in one more than 30° The deform ty developed postoperat vely in only four knees
21 knees had no deform ty preoperatively or at follow-up The deformity was corrected or d m nished in 23 knees, unchanged in 11 and increased in seven

The need for support at walking was reduced in 19 knees, unchanged in 25 and increased in 23. The failure to reduce the use of walking aids after knee arthroplasty was partly caused by pain at weight-bearing in other joints.

Table 5.
Extension defect.

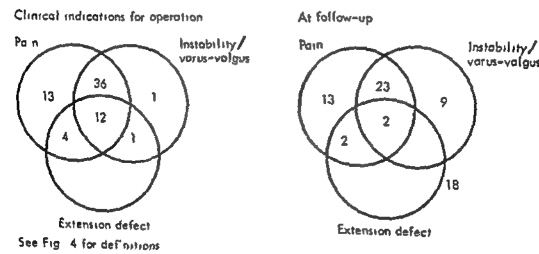
Points	0	1	2	4	Sum	
Follow-up	47	15	4	0		
4	1				1	
2	12	3	1		16	Preop.
1	16	9	3		28	
0	18	3			21	

Correction of preoperative extension defect was achieved in 29 of 45 knees, in three an improvement was noted. In 28 knees the extension defect was unchanged and in six increased.

Table 6.
Flexion.

Points	0	1	3	Sum	
Follow-up	51	11	4		
3	0	0	0	0	
1	2	1	1	4	Preop.
0	49	10	3	62	

In Weinfeld s evaluation system the limit for acceptable flexion is set at 80° A limit of 100° would probably be better as this is the minimum requ rement for negotiating stairs and for rising from chairs. Flexion less than 80° was only present in four knees preoperatively and in none it was considered as an indication for arthroplasty Postoperatively flexion less than 80° was present in 15 knees. The deterioration in flexion was significant.



In classifying the knees at follow-up 12 were excellent, 11 good, 14 fair and 30 poor By simplifying the system into only two groups to facilitate statistical analysis of the material, 23 knees were satisfactory (0-6 points) and 44 not satisfactory" (7-33 points).

When comparing the status preoperatively with that at follow-up for the individual knee, excluding factors that could not be correlated because of insufficient data (quadriceps power preoperatively in 35 knees), it was noted that, of the 44 knees with a not satisfactory result, 27 were improved, 4 unchanged and 13 worse.

Clinical indicat ons for operation and results at follow-up

The clinical indications for operation and findings at follow-up were compared with s m lar parameters in Venn diagrams to illustrate the effect of arthroplasty.

Fig 8

See Fig 4 for def nitions

Preoperatively all knees were within the diagram, at follow-up, 18 knees lie outs de the d agram those knees were without cons derable clinical symptoms At follow-up, there were 25 knees less with pain. The comb nation extension defect and pa n was reduced from 16 to 4 and the combination pain and instability and/or varus-valgus malposition was reduced from 48 to 25

Table 8.

Quadriceps power.

Preop. points	Follow-up 13	8	7	5	Sum
4	4	2	4	5	15
2	8	4	3		15
1					0
0	1				1
Points	0	1	2	4	

Conclusion of results according to Weinfeld

For each of the seven parameters, the average point score preoperatively and at follow-up was calculated on the basis of the number of corresponding observations.

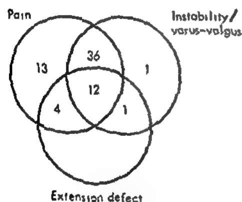
Table 9.

Score according to Weinfeld for the McIntosh material preoperatively and at follow-up.

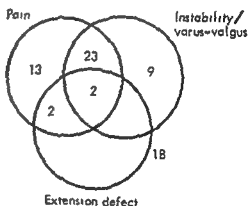
	Preoperatively	Follow-up	Number of corresponding observations	Wilcoxon's SRT p
Pain (0-7 points)	6.1	3 3	67	< 0.01
Use of support at walking (0-4 points)	1.9	2.1	67	0.788
Extension defect (0-4 points)	1.0	0.3	66	<0.001
Flexion (0-6 points)	0.0	0.3	66	<0.05 (worse)
Medial or lateral instability (0-4 points)	1.4	0 8	61	<0.001
Varus-valgus on weight-bearing (0-4 points)	1.2	0.7	64	<0.05
Quadriceps power (0-4 points)	2.9	1.3	31	<0.001
Sum demerit points	14.5	8.8		

The average demerit points was 14.5 preoperatively and 8.8 at follow-up. The score was thus reduced by 39 %.

At follow-up reduction in pain and improvement of extension and lateral stability were noted. Quadriceps power increased and varus or valgus on weight-bearing was reduced. Against this, a moderate reduction of flexion and an increased need for support in walking was noted. The reduction of flexion was less than the improvement of extension achieved. Movement was therefore improved within the important range 0-80°



In classifying the knees at follow-up 12 were excellent, 11 good, 14 fair and 30 poor. By simplifying the system into only two groups to facilitate statistical analysis of the material, 23 knees were satisfactory (0-6 points) and 44 not satisfactory' (7-33 points).



When comparing the status preoperatively with that at follow-up for the individual knee, excluding factors that could not be correlated because of insufficient data (quadriceps power preoperatively in 35 knees), it was noted that, of the 44 knees with a 'not satisfactory result, 27 were improved, 4 unchanged and 13 worse.

Clinical indications for operation and results at follow-up

The clinical indications for operation and findings at follow-up were compared with similar parameters in Venn diagrams to illustrate the effect of arthroplasty

Fig. 8

See Fig. 4 for definitions.

Preoperatively, all knees were within the diagram, at follow-up, 18 knees l e outside the diagram those knees were without considerable clinical symptoms. At follow-up, there were 25 knees less with pain The combination extension defect and pain was reduced from 16 to 4 and the combination pain and instability and/or varus-valgus malposition was reduced from 48 to 25

EFFECT OF COMPLICATIONS ON FINAL RESULTS

("Satisfactory" implies a Weinfeld score 0-6)

	No. of knees	"Satisfactory"	"Not satisfactory"
Operative complications	25	5	20
Loosening of insertion of ant. cruciate lig.	7	1	6
Cysts in tibial condyle	7	1	6
Wrong size of prosthesis	5	-	5
Incongruence	2	-	2
Others	4	3	1
Postoperative complications (within two months)	8	2	6
Complicated wound healing	4	-	4
Dislocation of the patella	1	-	1
Dislocation of the prosthesis	1	-	1
Others	2	2	-
Late complications (after two months)	8	2	6
Supracondylar femur fracture	2	2	-
Dislocation of the patella	1	-	1
Dislocation of the prosthesis	2	-	2
Collapse of the condyles	3	-	3

PREOPERATIVE ROENTGEN FINDINGS RELATED TO RESULTS

The numbers in parentheses after the number of knees in the tables show the number of "not satisfactory" results at follow-up to indicate the prognostic value.

Table 10.
Reduction of cartilage and attrition in FT-joints preoperatively

Narrowing of the articular space	5 (3)
Obliteration of the articular space	36 (21)
Attrition	22 (19)

(Insufficient data 4)

Result at follow-up were significantly poorer when attrition was present in one or both compartments (Chi^2 p 0.024)

On the basis of the description of cartilage and bone attrition at operation, the material was divided into three grades according to the degree of destruction. The gradings were chosen to enable direct comparison with the roentgen evaluation In 34 knees the clinical and roentgen assessment of the destruction was equal, in 22 the destruction according to the operative findings was more pronounced compared to the roentgen examination and in seven the operative findings were less than was expected. A *significant correlation* was found between the preoperative roentgen examination and the destruction as found at surgery (Chi^2 p = 0 029)

Table 11.
Reduction of cartilage and attrition in FP-joints preoperatively.

Normal height of cartilage >3 mm	25 (15)
Reduction of cartilage 0-3 mm	26 (18)
Attrition	11 (9)

(Insufficient data 5)

With attrition in the FP-joint the final results were "not satisfactory" in 9 of 11 knees. Significant correlation could not be proved

Table 12.
FTP-angle on varus and valgus provocation preoperatively.

>180°	10 (8)
180-168°	9 (1)
167-163°	20 (11)
<163°	17 (14)

(Insufficient data 11)

The best results at follow-up were in knees that preoperatively had an FTP-angle within the normal range, in 8 of 9 knees a 'satisfactory' result was obtained.

Even for knees in slight valgus, the result was quite acceptable. At an FTP-angle between 163 and 180°, the result was significantly better at follow-up than in knees with an FTP-angle outside this range (Chi^2 p = 0.002)

Table 13.
FTP-angle difference on varus and valgus provocation preoperatively.

FTP-angle difference <5°	25 (13)
FTP-angle difference ≧5°	32 (24)

(Inadequate data 10)

The FTP-angle difference was used as an indication of stability, even if there were considerable errors in method. Poorer results were seen when the FTP-angle difference exceeded 5° (Chi^2 p = 0 07) Correlation between an FTP-angle difference and degree of cartilage reduction and attrition, as judged at operation or by analysis of the roentgen material preoperatively were found (Chi^2 p = 0.029 and Chi^2 p = 0 014). Those correlations that reflect what should be expected indicate that the method error on measuring the FTP-angle difference was not too important.

ROENTGEN EXAMINATIONS AND RESULTS AT FOLLOW-UP

(Numbers in parentheses show the not satisfactory results at follow-up)

Table 14
Attrition of femur condyles at follow-up

Only those with an obviously changed configuration of the femoral condyles or attrition were cons dered pathological.

Normal configuration of femur condyles	43 (26)
Attrition or changed configuration	19 (15)

(Inadequate data 5)

The result was significantly poorer with attrition or changed configuration of the femoral condyles (Chi^2 p = 0.025).

Table 15.
FTP-angle on varus and valgus provocation at follow-up.

>180°	7 (5)
180-168°	26 (10)
167-163°	14 (12)
<163°	9 (8)

(Inadequate data 11)

The result was significantly better at follow-up when the FTP-angle in provocation was within the normal range (168-180°) (Chi^2 $p \approx 0.0005$).

Table 16.
FTP-angle difference on varus and valgus provocation at follow-up.

FTP-angle difference <5°	38 (18)
FTP-angle difference ≧5°	17 (16)

(Inadequate data 12)

At an FTP-angle difference exceeding 5° significantly poorer results were noticed (Chi^2 $p \sim 0.001$)

Table 17.
Position of prosthesis at follow-up.

Most pronounced displacement of the most dislocated prosthesis	
Lateral shift > 5 mm ≦ 10 mm	2 (2)
Lateral inclination > 5° ≦ 10°	7 (5)
Lateral inclination > 10° ≦ 20°	4 (3)
Anterior inclination > 5° ≦ 10°	6 (6)
Horizontal rotation more than 20°	1 (0)
Severe dislocation Inclination >20° or lateral shift >10 mm	10 (10)
Displacement	30 (26)
No displacement	34 (17)

(Inadequate data 3)

Only 4 of 30 knees with displacement of one or both prostheses had a *"satisfactory"*

The best results at follow-up were in knees that preoperatively had an FTP-angle within the normal range; in 8 of 9 knees a "satisfactory" result was obtained.

Even for knees in slight valgus, the result was quite acceptable. At an FTP-angle between 163 and 180°, the result was significantly better at follow-up than in knees with an FTP-angle outside this range (Chi^2: $p = 0.002$).

Table 13.
FTP-angle difference on varus and valgus provocation preoperatively.

FTP-angle difference <5°	25 (13)
FTP-angle difference ≥5°	32 (24)

(Inadequate data: 10)

The FTP-angle difference was used as an indication of stability, even if there were considerable errors in method. Poorer results were seen when the FTP-angle difference exceeded 5° (Chi^2: $p = 0.07$). Correlation between an FTP-angle difference and degree of cartilage reduction and attrition, as judged at operation or by analysis of the roentgen material preoperatively were found (Chi^2: $p = 0.029$ and Chi^2: $p = 0.014$). Those correlations that reflect what should be expected indicate that the method error on measuring the FTP-angle difference was not too important.

ROENTGEN EXAMINATIONS AND RESULTS AT FOLLOW-UP

(Numbers in parentheses show the "not satisfactory" results at follow-up).

Table 14.
Attrition of femur condyles at follow-up.

Only those with an obviously changed configuration of the femoral condyles or attrition were considered pathological.

Normal configuration of femur condyles	43 (26)
Attrition or changed configuration	19 (15)

(Inadequate data: 5)

The result was significantly poorer with attrition or changed configuration of the femoral condyles (Chi^2: $p = 0.025$).

tients opinion at follow-up

patients regretted having had the operation and 52 thought that they had benefited by the operation. All knees that in the opinion of the patients were unacceptable had according to Weinfeld s point system a "not satisfactory result. The average score for this group was 15 points against 8.4 points for the others. The reason for the patients' disappointment in 13 knees was pain at rest or immediately at weight-bearing.

To obtain a more precise idea of the patients impression of the result, the following four possibilities were suggested

Table 18.

Almost normal	7
Improved	44
Unaltered	11
Deteriorated	5

Statistical correlation could be shown between the patients opinion and the evaluation result according to Weinfeld (Chi^2 p = 0 0003).
There was also a statistical correlation between patients opinion and pain at follow-up (Chi^2 p = 0 007).

ARA function class

All patients were graded both *preoperatively and at follow-up* according to the American *Rheumatoid Arthritis Function Class System (Class I Manage without help, to Class IV: Totally dependent)* This system was modified by dividing class III into subgroups a and b. Patients in subgroup IIIa *were* considered stable enough *to remain in this class* with continued *rheumatological treatment*, patients in subgroup IIIb *(patients at risk) were likely to deteriorate to group IV unless surgery was undertaken.* Functional classification depends on the status *of the entire locomotor* system and can *alter with* disease activity as well as therapy during the observation time

result at follow-up. When no dislocation was noted, 17 of 34 knees had ■ "satisfactory" result. The 10 knees with severe dislocation had ■ 'not satisfactory" result at follow-up. The result was significantly poorer when displacement was present ($Chi^2 \cdot p = 0.002$).

When comparing the position of the prosthesis at follow-up and immediately postoperatively, it was found that in 10 knees the displacement was present immediately postoperatively. In 11 knees a slight displacement was present postoperatively but this increased during the observation time. In nine knees, the position of the prosthesis was normal immediately postoperatively, but the increased displacement developed during the observation time. The most usual displacement immediately postoperatively was an anterior inclination of one or both prostheses due to compensating for ■ preoperative extension defect.

Fig. 9. Postoperative subluxation of patella secondary to subluxation laterally and outward rotation of tibia.

Fig. 10. Pronounced displacement of the prosthesis and lateral subluxation of the tibia.

Fig. 11. Dislocation of the medial prosthesis to the lateral compartment.

atients opinion at follow-up

5 patients regretted having had the operation and 52 thought that they had benefited by ne operation All knees that in the opinion of the patients were unacceptable had ccording to Weinfeld s point system a "not satisfactory result The average score for his group was 15 points against 8 4 points for the others. The reason for the patients' lisappointment in 13 knees was pain at rest or immediately at weight-bearing.

To obtain a more precise idea of the patients impression of the result, the following four possibilities were suggested

Table 18.

Almost normal	7
Improved	44
Unaltered	11
Deteriorated	5

Statistical correlation could be shown between the patients' opinion and the evaluation result according to Weinfeld (Chi^2 $p = 0.0003$)
There was also a statistical correlation between patients opinion and pain at follow-up (Chi^2 $p = 0.007$).

ARA function class

All patients were graded both preoperatively and at follow-up according to the American Rheumatoid Arthritis Function Class System (Class I Manage without help, to Class IV Totally dependent). This system was modified by dividing class III into subgroups a and b. Patients in subgroup IIIa were considered stable enough to remain in this class with continued rheumatolog cal treatment, patients in subgroup IIIb (patients at risk) were likely to deteriorate to group IV unless surgery was undertaken. Functional classification depends on the status of the entire locomotor system and can alter with disease activity as well as therapy during the observation time

result at follow-up. When no dislocation was noted, 17 of 34 knees had a "satisfactory" result. The 10 knees with severe dislocation had a "not satisfactory" result at follow-up. The result was significantly poorer when displacement was present (Chi^2: p = 0.002).

When comparing the position of the prosthesis at follow-up and immediately postoperatively, it was found that in 10 knees the displacement was present immediately postoperatively. In 11 knees a slight displacement was present postoperatively but this increased during the observation time. In nine knees, the position of the prosthesis was normal immediately postoperatively, but the increased displacement developed during the observation time. The most usual displacement immediately postoperatively was an anterior inclination of one or both prostheses due to compensating for a preoperative extension defect.

e indications for operation with a hem prosthesis in the 10 materials referred to were in ccordance with the indications used in the Lund material.

ontraindications to McIntosh arthroplasty

ontraindications varied in different publ shed materials. McIntosh (1971) found it tech-nically possible at surgery to compensate for an extension defect up to 40° by loosening he insertion of the posterior capsule to the tibia and by resection of a ridge on the emoral condyles moreover, if the cruciate ligaments obstructed extension they could be esected. In most reports, lower values of an extension defect were regarded as a contra-ind cation. Kenwright and Duthie (1971) and Jani and Morscher (1973) accepted only 20°, Andersson et al (1973), Hastings and Hewitson (1973), Potter (1972) and Mowat et al. (1973) accepted up to 30° In the Lund material up to 30° were accepted and no correla-t on was observed between the degree of extension defect preoperatively and the result at follow-up

McIntosh (1971), Potter (1972), Nelson and Evarts (1971) considered 30° of varus or valgus as a contraindication Andersson et al. (1973), Neville and Martins (1972) and Mowat et al (1973) only accepted 20° Subluxation of the tib a was considered a contra-ndication by Jani and Morscher (1973), McIntosh (1971) and Potter (1969) In the Lund material, up to 30° of valgus or varus on weight-bearing was accepted. Significant corre-lat on between valgus or varus and result at follow-up was not found On measuring angles on frontal roentgen exposures at weight-bearing and provocat on so that the great-est divergence from 174° was registered in varus or valgus provocation, a "satisfactory" result was found at follow-up in 8 of 9 knees with an FTP-angle between 168 and 180°. At an FTP-angle exceed ng 180° or less than 163°, the result was significantly worse.

Kenwright and Duthie (1971), McIntosh (1974), and Nelson and Evarts (1971) considered predom nant destruction of the femoral condyles as a contra ndication for hemiarthro-plasty Neville and Martins (1972) only accepted 5 mm reduction of the femoral condyles. In the Lund material, obvious deformation of the femoral condyles was a contraind cation. By reviewing the roentgen material at follow-up, patholog cal configuration of one or both femoral condyles in 19 knees was found and the result at follow-up was "satisfactory" in only four knees These changes in the femoral condyles ma nly developed after the arthroplasty and were believed to be caused by the articulation between an unelastic metal surface and abnormal cartilage at the femoral condyles

Potter (1969) found large subchondral cysts to be a contraind cation. In the Lund material, an unsatisfactory result was found in 6 of 7 knees with large subchondral cysts in the tibia at operation Andersson et al. (1973), Jani and Morscher (1973) and Nelson and Evarts

Table 19.

ARA	Preoperatively	Follow-up
II	3	7
IIIa	18	22
IIIb (risk)	30	22
IV	13	13

(Insufficient data 3)

Improved 21

Unchanged 33

Worse 10

The improvement was significant (Wilcoxon s SRT p = 0.029)

No significant change in the socio-economic situation as a result of arthroplasty in the knee was found, but it must be seen as most satisfactory that 55 of these very disabled patients still manage to live at home.

DISCUSSION

McIntosh arthroplasty in the Lund material resulted in 23 knees (34 %) with satisfactory and 44 (66 %) with not satisfactory results, using the Weinfeld point system at follow-up after an observation period of, on average, 3 3 years On the basis of 10 published materials (Andersson et al 1973, Blum et al. 1974, Conaty 1974, Hastings and Hewitson 1973, McIntosh and Hunter 1972, Jani and Morscher 1973, Jessop and Moor 1972, Neville and Martins 1972, Potter 1969, and Schorn et al. 1977) the frequency of good or excellent results in a total of 553 knees in pat ents with rheumato d arthritis can be calculated at 57 % (38-82 %) with average observation periods of 1 6-4 0 years. To compare different populations with different evaluation systems is of doubtful value, however (Andersson 1972). Jani and Morscher (1973) (11 knees with observation period 3 8 years) and Potter (95 knees with observation period 3 years) evaluated their materials using the Weinfeld point system and found satisfactory results in 82 % and 56 % respectively By using the evaluation criteria as reported by Blum et al. (1974) (51 knees followed for 1 6 years), only 16 % of the knees in the Lund material fulfilled the requirements for a good result, Blum et al. (1974), however, reported 43 % good result in their series The results of the Lund material thus seem to be inferior to other published works. This m ght be due to population differences, but can also be caused by differences in indications and contra-indications to surgery, the operative technique and postoperative treatment However

the indications for operation with a hemiprosthesis in the 10 materials referred to were in accordance with the indications used in the Lund material.

Contraindications to McIntosh arthroplasty

Contraindications varied in different published materials. McIntosh (1971) found it technically possible at surgery to compensate for an extension defect up to 40° by loosening the insertion of the posterior capsule to the tibia and by resection of a ridge on the femoral condyles, moreover, if the cruciate ligaments obstructed extension they could be resected. In most reports, lower values of an extension defect were regarded as a contraindication Kenwright and Duthie (1971) and Jani and Morscher (1973) accepted only 20°, Andersson et al. (1973), Hastings and Hewitson (1973), Potter (1972) and Mowat et al. (1973) accepted up to 30° In the Lund material up to 30° were accepted and no correlation was observed between the degree of extension defect preoperatively and the result at follow-up.

McIntosh (1971) Potter (1972), Nelson and Evarts (1971) considered 30° of varus or valgus as a contraindication Andersson et al. (1973), Neville and Martins (1972) and Mowat et al (1973) only accepted 20°. Subluxation of the tibia was considered a contraindication by Jani and Morscher (1973), McIntosh (1971) and Potter (1969). In the Lund material, up to 30° of valgus or varus on weight-bearing was accepted. Significant correlation between valgus or varus and result at follow-up was not found On measuring angles on frontal roentgen exposures at weight-bearing and provocation so that the greatest divergence from 174° was registered in varus or valgus provocation, a "satisfactory" result was found at follow-up in 8 of 9 knees with an FTP-angle between 168 and 180°. At an FTP-angle exceeding 180° or less than 163°, the result was significantly worse.

Kenwright and Duthie (1971), McIntosh (1974), and Nelson and Evarts (1971) considered predominant destruction of the femoral condyles as a contraindication for hemiarthroplasty. Neville and Martins (1972) only accepted 5 mm reduction of the femoral condyles. In the Lund material, obvious deformation of the femoral condyles was a contraindication. By reviewing the roentgen material at follow-up, pathological configuration of one or both femoral condyles in 19 knees was found and the result at follow-up was "satisfactory" in only four knees. These changes in the femoral condyles mainly developed after the arthroplasty and were believed to be caused by the articulation between an unelastic metal surface and abnormal cartilage at the femoral condyles.

Potter (1969) found large subchondral cysts to be a contraindication. In the Lund material, an unsatisfactory result was found in 6 of 7 knees with large subchondral cysts in the tibia at operation. Andersson et al. (1973), Jani and Morscher (1973) and Nelson and Evarts

Table 19.

(Insufficient data 3)

Improved 21

Unchanged 33

Worse 10

The improvement was significant (Wilcoxon s SRT p = 0.029)

No significant change in the socio-economic situation as a result of arthroplasty in the knee was found, but it must be seen as most satisfactory that 55 of these very disabled patients still manage to live at home.

DISCUSSION

McIntosh arthroplasty in the Lund material resulted in 23 knees (34 %) with 'satisfactory and 44 (66 %) with 'not satisfactory results, using the Weinfeld point system at follow-up after an observation period of, on average, 3.3 years. On the basis of 10 published materials (Andersson et al. 1973, Blum et al. 1974, Conaty 1974, Hastings and Hewitson 1973, McIntosh and Hunter 1972, Jani and Morscher 1973, Jessop and Moor 1972, Neville and Martins 1972, Potter 1969, and Schorn et al 1977) the frequency of good or excellent results in a total of 553 knees in patients with rheumatoid arthritis can be calculated at 57 % (38-82 %) with average observation periods of 1 6-4 [illegible] years. To compare different populations with different evaluation systems is of doubtful value, however (Andersson 1972). Jani and Morscher (1973) (11 knees with observation period 3 8 years) and Potter (95 knees with observation period 3 years) evaluated their materials using the Weinfeld point system and found satisfactory results in 82 % and 56 % respectively By using the evaluation criteria as reported by Blum et al. (1974) (51 knees followed for 1 6 years), only 16 % of the knees in the Lund material fulfilled the requirements for a good result, Blum et al. (1974), however, reported 43 % good result in their series The results of the Lund material thus seem to be inferior to other published works. This might be due to population differences, but can also be caused by differences in indications and contra-indications to surgery, the operative technique and postoperative treatment However

the indications for operation with a hemiprosthesis in the 10 materials referred to were in accordance with the indications used in the Lund material.

Contraindications to McIntosh arthroplasty

Contraindications varied in different published materials. McIntosh (1971) found it technically possible at surgery to compensate for an extension defect up to 40° by loosening the insertion of the posterior capsule to the tibia and by resection of a ridge on the femoral condyles moreover, if the cruciate ligaments obstructed extension they could be resected. In most reports, lower values of an extension defect were regarded as a contraindication. Kenwright and Duthie (1971) and Jani and Morscher (1973) accepted only 20°, Andersson et al. (1973), Hastings and Hewitson (1973), Potter (1972) and Mowat et al. (1973) accepted up to 30°. In the Lund material up to 30° were accepted and no correlation was observed between the degree of extension defect preoperatively and the result at follow-up

McIntosh (1971), Potter (1972), Nelson and Evarts (1971) considered 30° of varus or valgus as a contraindication. Andersson et al. (1973), Neville and Martins (1972) and Mowat et al (1973) only accepted 20°. Subluxation of the tibia was considered a contraindication by Jani and Morscher (1973), McIntosh (1971) and Potter (1969). In the Lund material, up to 30° of valgus or varus on weight-bearing was accepted. Significant correlation between valgus or varus and result at follow-up was not found. On measuring angles on frontal roentgen exposures at weight-bearing and provocation so that the greatest divergence from 174° was registered in varus or valgus provocation, a satisfactory" result was found at follow-up in 8 of 9 knees with an FTP-angle between 168 and 180°. At an FTP-angle exceeding 180° or less than 163°, the result was significantly worse.

Kenwright and Duthie (1971), McIntosh (1974), and Nelson and Evarts (1971) considered predominant destruction of the femoral condyles as a contraindication for hemiarthroplasty Neville and Martins (1972) only accepted 5 mm reduction of the femoral condyles. In the Lund material, obvious deformation of the femoral condyles was a contraindication. By reviewing the roentgen material at follow-up, pathological configuration of one or both femoral condyles in 19 knees was found and the result at follow-up was "satisfactory" in only four knees. These changes in the femoral condyles mainly developed after the arthroplasty and were believed to be caused by the articulation between an unelastic metal surface and abnormal cartilage at the femoral condyles.

Potter (1969) found large subchondral cysts to be a contraindication. In the Lund material, an unsatisfactory result was found in 6 of 7 knees with large subchondral cysts in the tibia at operation. Andersson et al. (1973), Jani and Morscher (1973) and Nelson and Evarts

(1971) considered extreme osteoporosis a contraindication. In the Lund material the degree of osteoporosis was not quantitatively measured, but where systemic cortisone therapy had been administered for some years preoperatively, results were no worse than in the rest of the material.

Other involved joints

Hastings and Hewitson (1973) considered poor function in the hip and foot joints a contraindication. In the Lund material at follow-up, pain was experienced by eight patients at weight-bearing in the ipsilateral hip and by 11 in the contralateral hip. In all cases where pain in the hips at weight-bearing was present, the result of the knee arthroplasty was "not satisfactory" at follow-up. In this material, pain at weight-bearing in the foot joints did not affect the result of the arthroplasty. In eight patients where arthrodesis in the contralateral knee was performed before the knee arthroplasty, the result of the arthroplasty in all cases was "not satisfactory".

Surgical approach

Most authors have recommended a medial parapatellar approach. Hastings and Hewitson (1973) recommended a lateral approach because of diminished damage to lymph drainage. Burrough et al. (1973) and Jessop and Moor (1972) recommended the use of two parapatellar incisions when prostheses were inserted in both compartments. In the Lund material a medial parapatellar incision was consistently used; the wound failed to heal within four weeks in only four knees. Detachment of the tibial tuberosity was recommended by McIntosh (1971) and Jessop and Moor (1972) in the presence of severe destruction of the knee. Hastings and Hewitson (1973) divided the patella tendon instead, because osteoporosis made detachment of the tibial tuberosity a hazardous procedure. Other authors found detachment of the tuberosity to be unnecessary. In the Lund material, the tibial tuberosity was detached in 20 knees; the operation was made technically easier by this approach, but convalescence was delayed because of the necessary postoperative immobilization and the high incidence of open mobilization. In spite of normal wound healing, absence of infection and a final result that did not differ from the rest of the material, there was a 50 % increase in the time spent in hospital.

Operative procedure

Neville and Martins (1972) found that synovectomy was contraindicated because of decreased postoperative mobility after synovectomy. McIntosh (1971) found that a synovitis often became inactive after arthroplasty and that synovectomy was indicated only in very active cases. Most other authors have consistently performed a synovectomy at arthroplasty. In the Lund material, synovectomy was consistently carried out. The operat'

time was hardly increased and the partial denervation of the joint (Kellgren and Samuel 1950) may have been an advantage during mobilization.

Opinions seem to differ considerably concerning management when pronounced destruction was found in the FP-joints. Most authors mentioned that patellectomy should be avoided if possible. The highest frequency of patellectomy was found in Murray s material (1967), 10 patellectomies in 20 arthroplasties. Keever (1959) recommended patella prosthesis, Potter (1969) recommended fascia lata plasty. In the Lund material, only osteophytes were removed and erosions scraped. Although reduction of cartilage or attrition was found in 37 of 62 knees, considerable FP-joint problems were noted in only two knees postoperatively and then associated with patella subluxation In 9 of 11 knees with preoperative attrition in FP-joints, results at follow-up were 'not satisfactory , however.

McIntosh (1971) recommended reshaping of the femoral condyles. Potter (1969) and several others claimed the importance of chiselling away the bony ridge on the anterior part of the femoral condyles which develops when flexion contracture is present and the anterior edge of the tibia impinges on the femoral condyles. Turner et al. (1972) considered the use of a femoral mould prosthesis to be indicated if the main part of the destruction was localized to the femoral condyles In the Lund material, hemiarthroplasty was not performed if the femoral condyles were severely deformed. Because of the usually thin eburnated cortical covering of the femoral condyles, the possibilities of remodelling the condyles were not considered realistic.

Bone cement was not routinely used in any of the reports referred to in this discussion, but the use of cement for filling defects in the tibia is recommended Kates, who developed a modification of the McIntosh prosthesis for fixation with bone cement, recommended the consistent use of cement. In the Lund mater al, fixation with bone cement was only used in 25 knees with increasing frequency during the latter years. Burrough et al (1973), McIntosh (1969) and Murray (1967) recommended insertion of a prosthesis into both compartments in rheumatoid arthritis regardless of the state of the least destroyed compartment Blum et al (1974), Conaty (1973) and Mowat et al (1973) recommended that a prosthesis be inserted only in one compartment if this achieves lateral stability and alignment In the Lund material, unicompartment operation was performed in 14 knees which were less destroyed preoperatively than those in which a bicompartment arthroplasty was carried out At follow-up equal results in uni- and bicompartment operations were found.

Postoperative management

Although the intentions were to achieve primary wound healing and as good mobility as

(1971) considered extreme osteoporosis a contraindication. In the Lund material the degree of osteoporosis was not quantitatively measured, but where systemic cortisone therapy had been administered for some years preoperatively, results were no worse than in the rest of the material.

Other involved joints

Hastings and Hewitson (1973) considered poor function in the hip and foot joints a contraindication. In the Lund material at follow-up, pain was experienced by eight patients at weight-bearing in the ipsilateral hip and by 11 in the contralateral hip. In all cases where pain in the hips at weight-bearing was present, the result of the knee arthroplasty was 'not satisfactory' at follow-up. In this material, pain at weight-bearing in the foot joints did not affect the result of the arthroplasty. In eight patients where arthrodesis in the contralateral knee was performed before the knee arthroplasty, the result of the arthroplasty in all cases was 'not satisfactory'.

Surgical approach

In the Lund material, unicompartment operation was performed in 14 knees which were less destroyed preoperatively than those in which a bicompartment arthroplasty was carried out. At follow-up equal results in uni- and bicompartment operations were found.

Postoperative management

Although the intentions were to achieve primary wound healing and as good mobility as

possible, not two authors have recommended the same postoperative regime. McIntosh (1971) used Jones's compression bandage and kept the knee extended for five days before flexion was permitted. Potter (1969) recommended flexion on the third day, but used a plaster cast to immobilize the knee at night for 8–12 weeks. Weight-bearing was permitted by McIntosh (1971) after 5–7 days. Potter (1969) considered that full weight-bearing was possible after three months. In the Lund material wound healing was not a major problem. From this point of view, passive flexion after three days had no harmful effects. When cement is not used to fix the prosthesis, it seems reasonable to delay flexion and weight-bearing until fibrous retention of the prosthesis has developed. At surgery, it was often observed that the prosthesis dislocated and that the anterior end of the prosthesis did elevate on flexing the knee. With osteoporosis impaction of the prosthesis into spongious bone is also likely. In this material a change in position of the prosthesis from the first postoperative examination to follow-up was found in 20 knees. The result at follow-up when there was displacement of the prosthesis was 'satisfactory' in only 4 of 30 knees, it was not known when displacement occurred, but some of the displacements might have been caused by the early mobilization.

Manipulation under anaesthesia

McIntosh (1971) recommended manipulation under anaesthesia if flexion had not exceeded 90° after two weeks, cortisone was simultaneously injected into the knee. In Potter's material (1969), manipulation under anaesthesia was carried out in one third of the operated knees. When the tibial tuberosity was detached, open manipulation after 2–3 weeks was considered an almost obligatory second stage and in this material it was done in 15 of 20 knees.

Of 47 knees operated without detachment of the tibial tuberosity, manipulation under anaesthesia was done in only five knees. In one of them, both prostheses were impacted into the tibia and a horizontal rotation of one of the prostheses developed with a marked impairment of mobility. Early and active mobilization was instituted partly to avoid the risks involved with manipulation.

Deep infection

In the 10 clinical materials previously referred to involving 553 RA knees, deep infection was reported in 24 (4 %). Only McIntosh and Hunter (1972) stated that they used irrigation with neomycine during surgery. Systemic antibiotics did not seem to have been used by any of the authors. In the Lund material, prophylactic antibiotics were not used, and despite this, no instance of deep infection was noted. The highest incidence of delayed wound healing or superficial infection was found in 10 of 51 knees in Blum's et al.

material (1974). In the Lund material, complicated wound healing was found in four knees (6 %).

SUMMARY

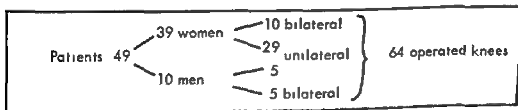
67 knees in 59 patients with RA were operated with the McIntosh prosthesis from 1967 to 1973

At follow-up 3.3 years postoperatively, an arbitrarily chosen degree of normalization of the knee, 0-6 points according to Weinfeld s evaluation system equal to a satisfactory" result, was achieved in 23 of 67 knees. Of 44 knees with seven or more points ("not satisfactory), an improvement was noted in 27 knees, unchanged in four and worse in 13. The arthroplasty led to a reduction in pain, d minished extension defect and correction of lateral instability Quadriceps power was increased and deformity at weight-bearing reduced A moderate reduction of flexion was noted. In 55 knees, an improvement was achieved in the patients opinion in 16, the knee was unchanged or worse than preoperatively A moderate but significant improvement of ARA functional classification occurred.

No fatal or life-threatening complications or deep infections were noted. A 'not satisfactory result was found in connection with accidential loosening of the anterior cruciate ligament, presence of large cysts in the tibia, incongruency after insertion of the prosthesis, and a prosthesis not large enough. Postoperative complications in the form of dislocation of the patella, dislocation of the prosthesis and collapse of the nonoperated compartment resulted in a high frequency of not satisfactory" results "Not satisfactory" results at follow-up were also found when malposition of the prosthesis was present, when valgus or varus deformity was present, if the FTP-angle difference was $\gtrless 5^{\circ}$ and when destruction of the femoral condyles develop postoperatively.

An improvement of results could obviously be achieved by stricter indications for the method Hemiarthroplasty gave poor results in patients who have been artrodesed in the opposite knee had pa n in the hips at weight-bearing, previous osteotomy or capsulotomy of the involved knee or who used a support to walk indoors preoperatively. There only remained a small group of patients with moderate pathological changes in the knee where late synovectomy could be a realistic alternative. Although the frequency of complications was acceptable at the time, McIntosh arthroplasty has nothing to recommend its use as a rational prosthetic alternative.

IV. GUEPAR ARTHROPLASTY



MATERIAL AND METHODS

The methods described in the introductory section p. 7 were only modified with regard to the prosthetic design. Postoperative roentgen examination at weight-bearing and provocation was not found to be of value because the mobility that developed on loosening of the prosthesis between cement and bone was so limited that the errors in FTP-angle measurements made the results unreliable. The postoperative roentgen examination aimed at *identification of prosthetic loosening and/or infection.*

To evaluate as early as possible the results of a Guépar arthroplasty, a preliminary postoperative examination was made after 12 months. During 1976-1977, an additional follow-up was carried out if at least six months had elapsed since the preliminary examination. In this way, 48 knees were examined on two occasions with on average 16 months (6-33) between examinations. In knees with complicated wound healing or suspected deep infection, case records were checked, and where indicated, the patient was re-examined in June 1978.

From 1972 through 1976, 49 patients, 39 women and 10 men, with RA were operated on with the Guépar prosthesis. Five men and 10 women were operated bilaterally making a total of 64 prostheses.

Fig. 12.

All operated knees were examined by the author and are included in the material.
Observation time averaged 2.7 years (1.1-4.3).
Average age at operation 63 years (29-77), women 65.4, men 54.3.

More than half of the patients had RA for more than 10 years before arthroplasty 53 knees were symptomatic for more than five years.

Table 20.
ESR preoperatively.

ESR mm/h	0-25	26-65	66-150
Knees	15	34	15

Previous treatment of the operated knee

Intra-articular cortisone. In 22 knees 1 to 10 cortisone injections were given and in 24 more than 10 injections, 18 were never treated with intra-articular cortisone.

Synovectomy Chemical synovectomy using osmium acid was carried out in seven knees and a combination of chemical and surgical synovectomy in 12 knees. Surgical synovectomy alone was done in seven knees making a total of 26 chemical and/or surgical synovectomies.

Capsulotomy was performed in four knees for correction of a flexion contracture.

High tibial osteotomy was carried out in five knees, two for correction of valgus, two for varus, and one for correction of an extreme flexion contracture.

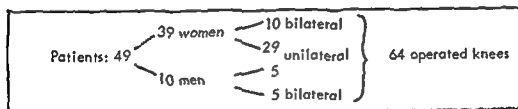
McIntosh arthroplasty. Eight previous McIntosh arthroplasties were converted to Guépar arthroplasties.

Marmor arthroplasty Two previous Marmor arthroplasties were converted to Guépar arthroplasties because of collapse of the medial tibial condyle and loosening with displacement of the prosthesis

Indications for operation

The indications for Guépar arthroplasty were changed during 1972-1976. When the prosthesis was introduced in 1972, there was a group of patients with extremely destroyed knees in which a McIntosh prosthesis would not have been sufficient for reconstruction. Because of the initially promising results following surgery, the indications for Guépar arthroplasty were considerably widened and from 1973 through 1974, it was also used in knees which previously would have been operated with a McIntosh prosthesis. Later, through our own experiences and reported complications following hinge joint arthroplasty, the indications were limited to the most severely destroyed knees.
No maximum limit for degree of deformity, subluxation between tibia and femur or extension defect was established, it was possible by means of sufficient bone resection to align the tibia and femur and obtain full extension.

IV. GUEPAR ARTHROPLASTY



MATERIAL AND METHODS

The methods described in the introductory section p. 7 were only modified with regard to the prosthetic design. Postoperative roentgen examination at weight-bearing and provocation was not found to be of value because the mobility that developed on loosening of the prosthesis between cement and bone was so limited that the errors in FTP-angle measurements made the results unreliable. The postoperative roentgen examination aimed at identification of prosthetic loosening and/or infection.

To evaluate as early as possible the results of a Guépar arthroplasty, a preliminary postoperative examination was made after 12 months. During 1976-1977, an additional follow-up was carried out if at least six months had elapsed since the preliminary examination. Marmor arthroplasty Two previous Marmor arthroplasties were converted to Guépar arthroplasties because of collapse of the med al tibial condyle and loosening with displacement of the prosthesis

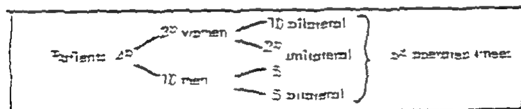
Ind cations for operation

The ind cations for Guépar arthroplasty were changed during 1972-1976. When the prosthesis was introduced in 1972, there was a group of pat ents with extremely destroyed knees in which a McIntosh prosthesis would not have been sufficient for reconstruction. Because of the initially prom sing results following surgery, the indications for Guépar arthroplasty were considerably widened and from 1973 through 1974, it was also used in knees which previously would have been operated with a McIntosh prosthesis. Later, through our own exper ences and reported compl cations following h nge joint arthroplasty, the ind cations were limited to the most severely destroyed knees.
No maximum limit for degree of deformity, subluxation between tibia and femur or extension defect was established, it was possible by means of suff cient bone resection to align the tib a and femur and obtain full extension.

IV. GUEPAR ARTHROPLASTY



MATERIAL AND METHODS

The methods described in the introductory section (p. 7) were only modified with regard to the prosthetic design. Postoperative roentgen examination at weight-bearing and [illegible] was not found to be of value because the [illegible] that developed on loosening of the prosthesis between cement and bone was so limited that the errors in FTA angle measurements made the results unreliable. The postoperative roentgen examination aimed at identification of prosthetic loosening and/or infection.

To evaluate as early as possible the results of a Guepar arthroplasty, a preliminary postoperative examination was made after 12 months. During 1975-1977, an additional follow-up was carried out if at least six months had elapsed since the preliminary examination. In this way, 45 knees were examined on two occasions with an average 16 months (6-33) between examinations. In knees with complicated wound healing or suspected deep infection, case records were checked, and where indicated, the patient was re-examined in June 1978.

From 1972 through 1976, 49 patients, 39 women and 10 men, with RA were operated on with the Guepar prosthesis. Five men and 10 women were operated bilaterally making a total of 64 prostheses.

Fig. [illegible]

All operated knees were examined by the author and are included in the material. Observation time averaged 2.7 years (1-4.3). Average age at operation 53 years (25-77), women [illegible], men [illegible].

More than half of the patients had RA for more than 10 years before arthroplasty. [illegible] knees were [illegible] for more than five years.

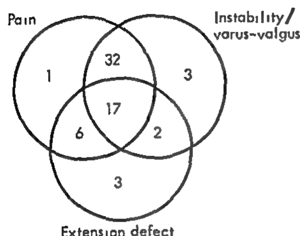
drained by a tube to prevent increasing pressure developing in the marrow cavity. Solucortef 100 mg was administered intravenously and the patient was ventilated with pure oxygen. These precautions were taken to prevent cardiopulmonary complications due to fat microembolism in the pulmonary capillaries (Olerud 1974). The femoral and tibial components were connected by the axle and the knee extended while the cement polymerized. Because of lateral dislocation of the patella during surgery and preoperative lateral rotation deformity in many knees the tibia had a tendency to rotate outwards. If the patella at this stage had a tendency to dislocate, a medial plication was done. A long-leg plaster cast was applied, and the bloodless field released. Vacuum drainage was applied and maintained for 24-48 hours.

Antibiotics. Prophylactic treatment with cloxacillin 1 g x 4 and probenecid 1 g x 2 was started before surgery and continued postoperatively for 10 days in 52 of 64 operations. In 12 operations no antibiotics were given before surgery or was discontinued earlier than 10 days because of secondary effects.

Anticoagulation therapy was not used routinely.

Postoperative treatment

The quadriceps was exercised from the first postoperative day and weight-bearing was permitted after 3-4 days. The plaster cast was removed at two weeks and active flexion began. If 90° flexion was not reached two weeks later manipulation under anaesthesia was performed, in this material in 34 knees.



COMPLICATIONS

Operative complications and technical difficulties

In 34 of 64 operations no technical difficulties or complications were encountered. The technique was modified or complications noted in 30 operations; In two operations two complications were noted.

Patella dislocation. In 17 knees lateralization of the patella occurred when the capsule was closed: in six the tibial tuberosity was transferred medially, in nine the lateral patella retinaculum was divided longitudinally (lateral release) and/or medial plication was performed. In one knee a left-side prosthesis was used in the right knee thus maintaining slight varus and diminishing the tendency of the patella to dislocate.

Fig. 13.
Clinical indication for Guépar arthroplasty in 64 knees.
See Fig. 4 for definition of subsets.

Pain was found in 56 knees (Fig. 13). In eight knees without pain, the main indication was instability and/or deformity in five and in three, an extension defect exceeding 30°. 54 knees were unstable and/or in varus or valgus exceeding 10°. In 28 knees there was an extension defect exceeding 15°. Decreased flexion was not of such degree as to constitute an indication.

Contraindications

Arthroplasty was not performed if there was a known focus of infection

Operative technique

One surgeon performed 51 operations and eight others performed 13 operations The operation was performed in a bloodless field under general or epidural anaesthesia A medial parapatellar incision was used and a synovectomy was carried out The collateral and cruciate ligaments were divided and the distal 15 mm of the femoral condyles resected so that the resected surface made a lateral open angle to the longitudinal axis of the femur of approximately 83°. The posterior aspect of the femoral condyles and the inferior part of the patella groove were removed. The proximal tibia was resected at a right angle to the longitudinal axis, making the total resection of femur and tibia approximately 18 mm or more for correction of flexion contractures. The position of the patella in relation to the depression on the femoral component was checked and if the patella dislocated laterally, a lateral release was performed and if necessary the tibial tuberosity was transferred medially. When inserting the cement the marrow cavities were

In three, infection with purulent secretion, local redness, swelling and tenderness were present Culture in two cases showed staph. aureus and in one E. coli. The infections healed with antibiotic therapy after 8, 26 and 28 weeks but antibiotics were continued for three months, one year and two years, respectively.

Table 21.
Predisposing factors for complicated wound healing.

	Complicated wound healing (13)	Normal wound healing (51)
Patella dislocation at surgery or post-operatively	8	13
Transfer of the tibial tuberosity	4	4
Previous knee operations	6	25
Cortisone preoperatively more than one year	5	25
No prophylactic antibiotics at surgery	2	10
Manipulation under anaesthesia	8	26

Analysis of possible reasons for complicated wound healing (Table 21) showed that transfer of the tibial tuberosity (Chi^2 p 0 026), patella dislocation at surgery or postoperatively (Chi^2 p 0 013) were significantly increased

Deep infection In one knee with uncomplicated wound healing, the knee became painful swollen and warm one month after operation No culture was taken, but because of the clinical picture, treatment with antibiotics was continued for six months. The patient d ed of unrelated disease one year after operation without signs of infection in the knee.

Patella dislocation In two knees with a tendency to patella dislocation at surgery, dislocation occurred postoperatively, although correction with lateral release and medial plication was performed at operation. Both knees were reoperated with a new medial plicat on

Peroneal palsy occurred after three operations. In one, the nerve was explored at six weeks and was found intact All three completely recovered

Pressure necros s over the achilles tendon. In one knee a pressure sore developed in the skin over the achilles tendon. The defect healed spontaneously.

Femoral fractures During physiotherapy, two weeks after manipulation under anaesthesia

Extension lag (relaxed patellar ligament). In four knees with preoperative flexion contracture and limited quadriceps amplitude, the patellar ligament was extremely slack after insertion of the prosthesis. In two of the knees the tibial tuberosity was transferred 3 cm distally to prevent an extension lag.

Fractures or perforations. Perforation of the femur (2) or tibia (3) caused by reaming or a insertion of the prosthetic components occurred in five knees but did not cause any majo weakening of the bone. Prolonged immobilization was not necessary and mobilization followed the normal routine. In one knee after a previous high tibial osteotomy, the medial tibial condyle was fractured and the tibia rotated 25° laterally when the prosthesis was cemented.

Loss of substance in tibial condyles. Severe destruction of the tibial condyles because of subchondral cysts was found in three knees. Most of the resection therefore was of the tibia. In one knee the loss of bone in the tibia was caused by a total collapse of the medial tibial condyle following a failed Marmor arthroplasty.

Wrong prosthesis. In one knee with extreme varus preoperatively, a right knee prosthesis was inserted in the left knee due to an error in labelling following sterilization. Most of the varus was however corrected and the prosthesis was therefore accepted.

Postoperative complications

General complications occurred in four patients and local complications in 21 knees.

General complications. Respiratory complications developed in three patients within the first week after the operation: lung embolus in one, pneumonia in two. The patients made an uneventful recovery following conventional therapy. In one case, a toxicodermi with fever developed caused by a previously unknown allergy against the prophylactic antibiotic.

Complicated wound healing – superficial infection. In 13 knees, the wound failed to heal within four weeks. In one a necrosis measuring 7 x 2 cm healed without surgery after six months. Several cultures were negative, but the surrounding tissue was red and warm. In four a defect of 0.5–2 cm with a serous secretion and negative culture was present. In one, blisters developed around the incision and culture showed β-streptococcus. In four, secretion continued from the wound for 4–8 weeks and positive culture was found (anaerobic streptococci, staph. epidermidis (two knees), aerobacter). All organisms cultured are usually found in normal skin and no signs of clinical infection were present. Antibiotic therapy was continued until the wound healed.

In three, infection with purulent secretion, local redness, swelling and tenderness were present. Culture in two cases showed staph. aureus and in one E. coli. The infections healed with antibiotic therapy after 8, 26 and 28 weeks but antibiotics were continued for three months, one year and two years, respectively.

Table 21.
Predisposing factors for complicated wound healing.

	Complicated wound healing (13)	Normal wound healing (51)
Patella dislocation at surgery or postoperatively	8	13
Transfer of the tibial tuberosity	4	4
Previous knee operations	6	25
Cortisone preoperatively more than one year	5	25
No prophylactic antibiotics at surgery	2	10
Manipulation under anaesthesia	8	26

Analysis of possible reasons for complicated wound healing (Table 21) showed that transfer of the tibial tuberosity (Chi^2 p 0.026), patella dislocation at surgery or postoperatively (Chi^2 p 0.013) were significantly increased.

Deep infection. In one knee with uncomplicated wound healing, the knee became painful swollen and warm one month after operation. No culture was taken, but because of the clinical picture, treatment with antibiotics was continued for six months. The patient died of unrelated disease one year after operation without signs of infection in the knee.

Patella dislocation. In two knees with a tendency to patella dislocation at surgery, dislocation occurred postoperatively, although correction with lateral release and medial plication was performed at operation. Both knees were reoperated with a new medial plication.

Peroneal palsy occurred after three operations. In one, the nerve was explored at six weeks and was found intact. All three completely recovered.

Pressure necrosis over the achilles tendon. In one knee a pressure sore developed in the skin over the achilles tendon. The defect healed spontaneously.

Femoral fractures. During physiotherapy, two weeks after manipulation under anaesthesia,

one patient experienced intense pain at the middle of the femur. Roentgen examination showed a fracture of the femoral diaphysis level with the tip of the prosthetic stem. This might have been due to an infraction during manipulation or a stress fracture. The fracture healed in balanced traction in eight weeks.

Duration of hospitalization. The average time spent in the Department of Orthopaedics or Rheumatology was 45 days (8–180). When complicated wound healing was present, the duration was increased on an average by 44 %.

Late complications

Complications registered later than two months after operation but within the observation time occurred in 21 knees.

Patella dislocation. In five knees, the patella dislocated on flexion, lateral to the trochlea on the femoral component (Fig 16a and b). In one knee, this dislocation caused pain on flexion and extension and a transfer of the tibial tuberosity was carried out. This reoperation was complicated by a superficial infection.

Fractures. A femoral shaft fracture occurred after a fall at home in a patient with a known late infection and a more than six mm broad radiolucent zone around the cement and loosening of the prosthesis (Fig. 17a and b), following immobilization the fracture healed without complications.

Late infection. Because of the importance of deep infection as a complication after hinge arthroplasty all knees with complicated wound healing or suspected deep infection, even when evident after the follow-up examination, were reviewed in June 1978. Evidence of late infection were found in 15 knees. The observation time was on average 4.6 years (2.1–6.0).

Diagnosis of late infection was based on a combined assessment of local clinical symptoms such as pain, swelling, redness and warmth, fistula and skin necrosis, and general signs of infection such as fever, leucocytosis, ESR and CRP elevation and bacteriological findings. Roentgen observations such as abnormal width and enlargement of radiolucent zones, scalloping and periosteal reaction were also considered. Scintimetry with Sr^{85} was done in most cases of suspected infection.

Appearance of late infection

Half of the late infections appeared within the first year after operation. After the first year, the cumulative curve became quite straight and was still rising. After five years, an additional infection was found and it seems reasonable to expect more in the future.

Table 22.

Initial manifestation of late infection.

Dolor, rubor, calor (2-3 months)	2
Fistula (12-41 months)	5
Septic arthritis (4-52 months)	3
Increasing radiolucent zone + pain at weight-bearing (11-62 months)	5

Two of the three patients that developed septic arthritis died of sepsis within one week despite intensive antibiotic therapy.

Table 23.

Result of culture.

No culture	2	
Culture from wound or fistula	*6*	*Anaerobic streptococci,* β-streptococci, staph. aureus, staph. albus + coliform rods, staph. aureus + gramnegative rods, clostridia
Aspiration of the knee	1	Negative
Fenestration of femur	1	Staph. aureus
Operative tissue culture at reoperation (6 samples in each case)	5	3 none isolated in 5-6 of 6 samples 1 Propione bact acne in 4 of 6 samples 1 Streptococci in 5 of 6 samples

According to Lindberg (1978), infection should be proved by taking six tissue samples from the suspected area when no antibiotics have been administered for six weeks. These requirements were fulfilled in only two knees, in one propsione bact. acne was found in 4 of 6 samples, and in the other β-streptococci was found in 5 of 6 samples. In one knee a fenestration was done, pus was present and culture showed staph. aureus which was considered the causative organism.

In six knees where no culture was made or no organism was identified but where the patient was under treatment with antibiotics when the culture material was obtained, infection could have been present. In six knees culture from the wound or fistula showed the abovementioned organisms which might have been the causative organism, but contamination could not be excluded.

one patient experienced intense pain at the middle of the femur. Roentgen examination showed a fracture of the femoral diaphysis level with the tip of the prosthetic stem. This might have been due to an infraction during manipulation or a stress fracture. The fracture healed in balanced traction in eight weeks.

Duration of hospitalization. The average time spent in the Department of Orthopaedics or Rheumatology was 45 days (8-180). When complicated wound healing was present, the duration was increased on an average by 44 %

Late complications

Complications registered later than two months after operation but within the observation time occurred in 21 knees.

Patella dislocation. In five knees, the patella dislocated on flexion, lateral to the trochlea on the femoral component (Fig 16a and b). In one knee, this dislocation caused pain on flexion and extension and a transfer of the tibial tuberosity was carried out. This reoperation was complicated by a superficial infection.

Fractures. A femoral shaft fracture occurred after a fall at home in a patient with a known late infection and a more than six mm broad radiolucent zone around the cement and loosening of the prosthesis (Fig. 17a and b), following immobilization the fracture healed without complications

Late infection Because of the importance of deep infection as a complication after hinge arthroplasty all knees with complicated wound healing or suspected deep infection, even when evident after the follow-up examination, were reviewed in June 1978. Evidence of late infection were found in 15 knees The observation time was on average 4.6 years (2 1-6 0).
Diagnosis of late infection was based on a combined assessment of local clinical symptoms such as pain, swelling, redness and warmth, fistula and skin necrosis, and general signs of infection such as fever, leucocytosis, ESR and CRP elevation and bacteriological findings. Roentgen observations such as abnormal width and enlargement of radiolucent zones, scalloping and periosteal reaction were also considered Scintimetry with Sr^{85} was done in most cases of suspected infection

Appearance of late infection

Half of the late infections appeared within the first year after operation After the first year, the cumulative curve became quite straight and was still rising After five years, an additional infection was found and it seems reasonable to expect more in the future

cement was chiselled away. After synovectomy and removal of all non-viable tissue, a new prosthesis was inserted with cement containing gentamycin.

Arthrodesis was carried out in one knee 61 months after the initial signs of infection. Observation time was too short to decide whether osseous healing would be achieved (Fig 18a and b)

Amputation. In one knee a fulminant septic arthritis developed within a few days 18 months after the arthroplasty. The prosthesis was removed, perfusion drainage instituted and intensive systemic antibiotic therapy started but septicaemia with toxic manifestations developed. On vital indication, an above-knee amputation was performed. The patient survived, has a lower limp prosthesis and a total hip arthroplasty in the contralateral hip performed without complications.

Status June 1978

Late infections were diagnosed in 15 knees in 13 patients. Two patients had died of septicaemia One above-knee amputation had been carried out (vide supra). Four had been reoperated with a change of prosthesis and were without signs of present infection. One of these four was still on antibiotics because of an infection in the other knee. One knee had been arthrodesed. One with a slowly progressive low virulent infection was due for a change of prosthesis. Three had no signs of infection more than one year after discontinuing antibiotics. One had a continuous infection in both knees and was on antibiotics.

The bacteriological diagnosis was thus definitely established in only three knees In 12 knees infection might have been present, but the causative *organism was not positively* identified.

Factors predisposing to deep infection

Complicated wound healing. In four knees with late infection, wound healing was not established four weeks after operation. Only one of them had a clinically superficial infection initially with a fistula in the tibial tuberosity area. Fistulography and exploration failed to show any communication with the joint. These four knees were treated with antibiotics for 2, 15, 17 and 48 months before the deep infection became manifest.

Antibiotic prophylaxis was used in 52 knees. Late infection developed in nine. In 12 knees, no prophylactic antibiotics were administered before surgery or was ended because of secondary reactions. Late infection developed in six. Prophylactic antibiotics significantly reduced the frequency of late infection

Transfer of the tibial tuberosity.In 5 of 15 knees with *a late* infection, *the tuberosity had* been transferred. In 49 knees without late infection, the tuberosity was only transferred in three. Transfer of the tuberosity significantly increased the frequency of late infection

Dislocation of the patella at surgery or postoperatively, previous knee operations and cortisone medication did not substantially predispose to late infection in this material.

Treatment of late infection

Treatment with antibiotics. Nine patients with 11 infected knees were treated with antibiotics from 6 to 60 months (average 27 months). Two patients with three infected knees were still under treatment with antib otics. These knees were almost pa nfree but the prostheses were clinically loose with instability, the patients condition precluded reoperation. In three knees, antibiotic treatment was discontinued, and more than 12 months had passed without signs of reinfection Because of progress of infection in spite of antibiotic treatment, five knees were reoperated.

Change of prosthesis. In four knees the prosthesis was removed in two, it was replaced with a new Guépar prosthesis, and in two with a Shier prosthesis. The reoperations were done 16, 17, 37 and 42 months after infection became manifest. The Shier prosthesis was chosen in two knees because the stems were longer than in the Guépar prosthesis When removing the infected prosthesis, a 1 cm wide groove was opened longitudinally in the femur and tibia until the tip of the cement was identified and through this channel all

three increased From the preliminary examination to follow-up, the need diminished in nine and increased in five When quadriceps power was less than 100N at follow-up, the need for support at walking significantly increased.

Table 26.
Extension defect.

	Follow-up 51	10	2		Sum	
4	4	3	1		8	
2	19	1			20	Preop.
1	14	2	1		17	
0	14	4			18	
Points	0	1	2	4		

Arthroplasty reduced or eliminated the extension defect in 42 knees, left it unchanged in two, and increased it in five From preliminary examination to follow-up, it increased in nine and was reduced in three No correlation could be shown between extension defect at follow-up and decreased quadriceps power.

Table 27.
Flexion.

	Follow-up 50	8	4	1	Sum	
6		1			1

0	43	4	3	1	51	
Points	0	1	3	6		

Flexion less than 80° was found preoperatively in 12 knees. Of these, an improvement of flexion was found in nine Flexion less than 80° was found in 13 postoperatively. Of these, the flexion had been reduced in nine From the preliminary examination to follow-up, flexion increased in six and was reduced in one.

FOLLOW-UP EVALUATION

The seven parameters in Weinfeld s evaluation system (see page 9) formed the basis for the evaluation of status preoperatively and at follow-up.

Table 24.
Pain.

Preop. points	Follow-up: 43	4	5	6	5	Sum
7	26	2	3	4	5	40
6	9	2	2	2		15
3						
1						
0	8					8
Points	0	1	3	6	7	

Pain at rest or immediately at weight-bearing was an important indication for operation in 55 knees, 35 of them were painfree after operation and in 13 knees, pain was d minished. In 16 knees pain on walking was present at follow-up. From the preliminary exam nation to follow-up approximately 12 months after operation (48 knees examined) pain increased in eight knees and diminished in 10
An analysis of the reasons for pain at follow-up in 16 knees on less than 200 m walking showed a high incidence of tibial tuberosity transfer, dislocation of the patella at surgery and postoperatively and complicated wound healing. No increase in pain was found in relation to late infection However, no significance can be attached to these factors even though occurring more than twice as much in the group w th pain

Table 25.
Use of support at walking.

Preop. points	Follow-up: 15	9	10	30	Sum
4	8	3	5	27	43
2		6	5	3	14
1					0
0	7				7
Points	0	1	2	4	

In 22 knees the need for support at walking was diminished, in 39 unchanged and in

In 40 knees with considerable varus (24 knees) or valgus (16 knees) preoperatively, the FT-angle on weight-bearing was corrected to 164-184°. Only four knees had valgus of 10 to 20° at follow-up. This was caused in three by the stems of the prostheses abutting against the lateral cortex and in one, by late infection with loosening and marked resorption around the bone cement.

Table 29.
Quadriceps power.

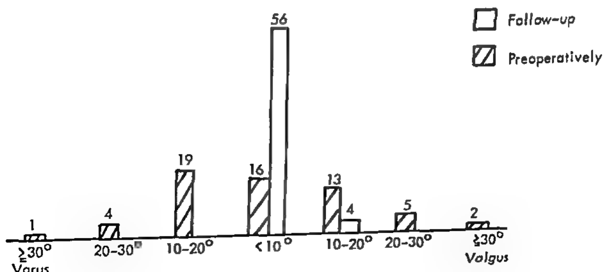
4	6	2	15	14	37
[illegible]	2	2	2	3	9 Preop.
1					
0					

The quadriceps power was improved in 27 of 46 knees but power exceeding 200N was reached in only eight. The quadriceps power was registered at the preliminary examination approximately one year after the operation and at follow-up on average 16 months later. A comparison of the quadriceps power on these two occasions showed an improvement in two knees, no change in 25, and a reduction in 24. This reduction was significant (Wilcoxon s SRT $p < 0.0001$), many patients on testing experienced considerable, deep and intensive pain, which often continued for several hours afterwards.

Conclusion of results according to Weinfeld



For each of the seven parameters, the average point score preoperatively and at follow-up was calculated on the basis of the number of observations.

Table 28.
Medial or lateral instability.

	Follow-up 58	2	1	Sum	
4	12			12	
2	36		1	37	Preop.
0	10	2		12	
Points	0	2	4		

Arthroplasty eliminated preoperative instability in 48 of 49 knees. At follow-up, instability exceeding 10° was found in three knees. Of the 58 knees with less than 10° lateral or medial instability, a very limited (less than 5°) mobility was registered when the observation time exceeded two years. This mobility, obviously present but not of a magnitude that permitted reliable measurement, could be caused by wear of the prostheses, or what is probably more relevant, mobility between cement and bone because of *granulation tissue around the cement, which roentgenologically is visualized as a radiolucent zone.* From preliminary examination to follow-up, medial or lateral instability ≧10° developed in three knees. Late infection with loosening of the prosthesis was the cause of instability in these knees.

Fig. 19.
Varus-valgus deformity at weight-bearing (clinical).

In 40 knees with considerable varus (24 knees) or valgus (16 knees) preoperatively, the FT-angle on weight-bearing was corrected to 164-184°. Only four knees had valgus of 10 to 20° at follow-up. This was caused in three by the stems of the prostheses abutting against the lateral cortex and in one, by late infection with loosening and marked resorption around the bone cement.

The quadriceps power was improved in 27 of 46 knees but power exceeding 200N was reached in only eight. The quadriceps power was registered at the preliminary examination approximately one year after the operation and at follow-up on average 16 months later. A comparison of the quadriceps power on these two occasions showed an improvement in two knees, no change in 25, and a reduction in 24. This reduction was significant (Wilcoxon's SRT $p<0.0001$), many patients on testing experienced considerable, deep and intensive pain, which often continued for several hours afterwards.

Conclusion of results according to Weinfeld

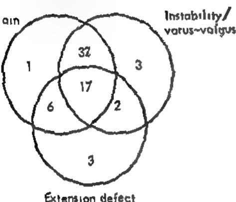
For each of the seven parameters, the average point score preoperatively and at follow-up was calculated on the basis of the number of observations.

Table 30.
Score according to Weinfeld for the Guépar material preoperatively, at the preliminary examination and at follow-up.

	Pre-operatively	Preliminary examination (48)	Follow-up	Number of observations	Significant improvement (p)[x]
Pain (0-7 points)	5.9	1.5	1.3	63	<0.001
Use of support at walking (0-4 points)	3.1	2.6	2.3	64	<0.001
Extension defect (0-4 points)	1.4	0.1	0.2	63	<0.0001
Flexion (0-6 points)	0.3	0.6	0.4	63	0.523
Medial or lateral instability (0-4 points)	2.0	0.0	0.1	61	<0.0001
Varus-valgus at weight-bearing (0-4 points)	1.7	0.1	0.1	60	<0.0001
Quadriceps power (0-4 points)	3.5	1.4	2.3	46	<0.001
Sum demerit points	17.9	6.3	6.7		

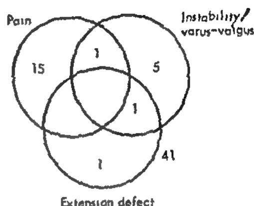
[x] From preoperative to follow-up status.

The average demerit points was 17.9 preoperatively against 6.7 at follow-up. The score was thus reduced by 63 %. Results at the preliminary examination of 48 knees approximately 12 months after operation was on average 6.3 points, which was 0.4 points better than average at the follow-up about 16 months later. The deterioration was caused by decreased quadriceps power at follow-up. On the basis of a comparison between average demerit points preoperatively and those at the three-year follow-up it can be concluded that the Guépar prosthesis has significantly reduced pain, need for support at walking, extension defect, lateral instability, varus-valgus deformity and quadriceps weakness. Flexion has not been significantly reduced.



On the basis of Weinfeld's evaluation system, the score at follow-up in 10 knees was excellent, 20 good, 20 fair and 14 poor. By simplifying the system into only two groups, 30 knees had a "satisfactory" result (0-6 points) and 34 a "not satisfactory" result (7-33 points). When comparing the status preoperatively and at follow-up for the individual knee with the exclusion of parameters that cannot be correlated because of inadequate data (quadriceps power preoperatively in 18 knees), it was found that 31 of the 34 knees with a "not satisfactory" result were improved, two unchanged, and one worse. The considerable improvement reached even in this group could be confirmed by the patients' own judgement, 29 knees improved, two unchanged and three worse.

linical indication for operation and result at follow-up



linical indications for operation and findings at follow-up were compared with similar arameters at follow-up in a Venn diagram.

ig. 20.
ee Fig. 4 for definition of subsets.

reoperative status

Follow-up status

Preoperatively 57 of 64 knees had a combination of two or three parameters. At follow-up, 41 knees were outs de the diagram and only two knees still had a combination of two of the preoperative parameters. Guépar arthroplasty was less effective in eliminating pain. In three of the seven knees at follow-up with lateral instability and/or malposition in varus or valgus prosthetic loosening caused by infection was responsible.

EFFECT OF COMPLICATIONS ON FINAL RESULTS

("Satisfactory" implies a Weinfeld score 0-6)

	No. of knees	"Satisfactory	"Not satis-factory"
Operative complications	30	9	21
D slocation of the patella	17	4	13
Active insuff ciency of extensors	4	2	2
Fracture or perforation (t bia or femur)	7	-	7
Bony defects in tib al condyle	3	2	1
Wrong side prosthesis	1	1	-
No. of compl cations (2 complications were noted in 2 operations)	32		

	No. of knees	Satisfactory	Not satisfactory
Postoperative complications (within two months)	21	9	12
Delayed wound healing	13	5	8
Dislocation of the patella	2	-	2
Peroneal palsy	3	1	2
Others	3	3	-
Late complications (after two months)	21	5	16
Late infection	15	3	12
Dislocation of the patella	5	2	[illegible]
Fracture of the femur	1	-	1
Without complications	16	10	6

PREOPERATIVE ROENTGEN FINDINGS RELATED TO RESULTS

The numbers in parentheses indicate not satisfactory results at follow-up.
Obliteration of the articular space was found in 16 knees and attrition of FT-joints in 48. In 19 of the knees, attrition was combined with lateral subluxation of t bia in relation to femur. Results at follow-up were not related to the degree of observed destruction in FT-joints

Table 31.
Reduction of cartilage and attrition in FP-joints.

Height of cartilage > 3 mm	12 (6)
Reduction of cartilage 0-3 mm	23 (8)
Attrition	29 (20)

With attrition in the FP-jo nt, the result was found significantly worse at follow-up (Chi^{2} p = 0 021).

Table 32.
FTP-angle on varus/valgus provocation.

FTP > 180°	18 (7)
FTP 180-168°	15 (8)
FTP 167-163°	6 (4)
FTP < 163°	8 (6)

(Inadequate data 19)

Results at follow-up were better when the FTP-angle exceeded 180° and became gradually worse with decreasing FTP-angle (Chi^2 $p = 0.031$). Operative or postoperative dislocation of the patella was more common when the FTP-angle was < 168° but there was no significant correlation.

The FTP-angle difference on varus/valgus provocation were found to be without prognostic value.

ROENTGEN EXAMINATION AND RESULTS AT FOLLOW-UP

The aim of the analysis of the postoperative roentgen material was to demonstrate signs of prosthetic loosening and infection. The analysis was based on all existing roentgen material for each knee

Operative fractures and perforations

Fractures or perforations of the diaphysis at operation were demonstrated by the presence of extraosseous bone cement or the existence of loose fragments, callus formation or periosteal reaction were late signs of operative fractures. In six knees a perforation of the diaphysis was found two in the femur and four in the tibia. All perforations were localized near the point of the stem and probably occurred on reaming or inserting the prosthesis. There was no displacement in any of the fractures and healing was uneventful The result at follow-up was not satisfactory' in all six knees with perforation, although the prosthesis in only one knee was positioned with the point of the stem extraosseously (Fig. 15).

Position of prosthesis

Direct contact of the prosthetic stem with cortical bone occurred in four knees in the femur. 18 knees in the tibia and nine knees both proximally and distally. The result at

follow-up seemed not to be related to the position of the prosthesis in the medullary cavity.

Cement covering of the prosthetic stems

In 30 knees both stems were completely surrounded by cement and the results here were 'satisfactory' in 16. In 34 knees one or both prosthetic stems were not completely surrounded by cement and results here were 'satisfactory' in 14. The difference was not significant. An indication of the importance of surrounding the prosthetic stems for maximum fixation was the fact that the radiolucent zone, measured 12 months after operation, significantly more often exceeded 1 mm when the stems were not completely surrounded. This indicates that loosening of the prosthesis, although often of no major clinical importance, develops more rapidly in this group.

Demarcation zone

The demarcation zone was defined as the radiolucent zone which often developed postoperatively around the cement and parts of the prostheses in contact with bone and which was limited by a condensation of osseous tissue (internal cortex). To regard a wide radiolucent zone as being pathological, knowledge of the normal demarcation zone in relation to time was essential. It was therefore necessary to establish a normal material which excluded knees with deep infection, fracture or inadequate cementation of the prosthesis. This subset was extracted by the exclusion of knees having the following criteria

1) Pain on walking less than 200 m
2) Inadequate cementation of one or both prosthetic stems
3) Operative or postoperative fractures of the femur or tibia
4) Knees with known or suspected late infection

By this method 16 knees were extracted as a 'normal material'. All postoperative roentgen examinations for these knees were perused and the width of the zone was registered in relation to time following surgery.

In the 'normal material' the demarcation zone was less than 1 mm during the first four postoperative years, except in one knee where the demarcation zone was 1.5 mm after two years.

Demarcation zone after one year. In 58 knees the width of the demarcation zone registered at one year following surgery was between 1 and 2 mm in seven knees, 2-4 mm in five knees and 4-6 mm in three knees. 15 knees therefore had a demarcation zone after one year which exceeded 'normal' expectations.

Of the 15 knees with a demarcation zone exceeding 1 mm after one year, the cement surrounding one or both prosthetic stems was inadequate in 12. Late infection was present in five of them and in three, pain was present on walking less than 200 m. In three with adequate cementation of the prosthesis, no presence of late infection and no pain on weight-bearing the cause of a wide demarcation zone was obscure. Significant correlation was found between a wide demarcation zone and inadequate cementation of prosthesis (Chi^2 $p = 0.017$)

Demarcation zone in late infection

In 15 knees with late infection, the demarcation zone was measured in all roentgen examinations. In eight, the demarcation zone did not exceed 1 mm. This means that a normal demarcation zone did not exclude infection In seven knees with a late infection, the demarcation zone increased to more than 1 mm and in five of them progressive widening of the demarcation zone proved of practical value in establishing the diagnosis of infection

Scalloping - periosteal reaction

Scalloping means local widening of the radiolucent zone around the prosthesis (Sjöstrand 1974) In this material, scalloping was seen in three knees, 1.0-3.5 years postoperatively and late infection was present in all Periosteal reaction on a level with one of the points of prosthetic stems was seen in eight knees

Late infection was present in 6 of 11 knees with scalloping and/or periosteal reaction. In these the demarcation zone exceeded 1 mm at examination one year postoperatively in three knees The role of infection in the development of periosteal reaction or scalloping was difficult to evaluate because 9 of the 11 knees with scalloping and/or periosteal reaction did not have sufficient cement surrounding on one or both prosthetic stems and therefore an inadequate cementation of the prosthesis may have accounted for the periosteal reaction. A fracture was seen in only one knee with scalloping and a persistent periosteal reaction and a demarcation zone of more than 6 mm wide with deep infection (Fig 17a and b) In three knees, a normal demarcation zone was found with no late infection or fractures present, but a periosteal reaction, level with the tip of the prosthetic stem In one of these knees the prosthesis was not sufficiently surrounded by cement and in the other two, the tip of the stem was in contact with cortical bone, the periosteal reaction was considered a stress phenomenon.

Patients opinion at follow-up

Three patients stated that they would have refused operation had they known the outcome. 61 patients were satisfied with the operation at the time of follow-up. Of the

follow-up seemed not to be related to the position of the prosthesis in the medullary cavity.

Cement covering of the prosthetic stems

In 30 knees both stems were completely surrounded by cement and the results here were "satisfactory" in 16. In 34 knees one or both prosthetic stems were not completely surrounded by cement and results here were "satisfactory" in 14. The difference was not significant. An indication of the importance of surrounding the prosthetic stems for maximum fixation was the fact that the radiolucent zone, measured 12 months after operation, significantly more often exceeded 1 mm when the stems were not completely surrounded. This indicates that loosening of the prosthesis, although often of no major clinical importance, develops more rapidly in this group.

Demarcation zone

The demarcation zone was defined as the radiolucent zone which often developed postoperatively around the cement and parts of the prostheses in contact with bone and which was limited by a condensation of osseous tissue (internal cortex). To regard a wide radiolucent zone as being pathological, knowledge of the normal demarcation zone in relation to time was essential. It was therefore necessary to establish a normal material which excluded knees with deep infection, fracture or inadequate cementation of the prosthesis. This subset was extracted by the exclusion of knees having the following criteria.

1) Pain on walking less than 200 m
2) Inadequate cementation of one or both prosthetic stems
3) Operative or postoperative fractures of the femur or tibia
4) Knees with known ur suspected late infection

By this method 16 knees were extracted as a "normal material". All postoperative roentgen examinations for these knees were perused and the width of the zone was registered in relation to time following surgery.

In the "normal material" the demarcation zone was less than 1 mm during the first four postoperative years, except in one knee where the demarcation zone was 1.5 mm after two years.

Demarcation zone after one year. In 58 knees the width of the demarcation zone registered at one year following surgery was between 1 and 2 mm in seven knees, 2-4 mm in five knees and 4-6 mm in three knees. 15 knees therefore had a demarcation zone after one year which exceeded "normal" expectations.

DISCUSSION

Following Guépar arthroplasty in the Lund material results were "satisfactory" in 30 knees and "not satisfactory" in 34 at follow-up 2.7 years (1.0-4.3) after operation. Clinical reports of Guépar arthroplasty in mixed materials of OA and RA were published by Deburge et al. (1976) including 103 RA knees with an observation time exceeding 24 months, Insall et al. (1976) 24 RA knees with an observation time exceeding 24 months, Sneppen et al. (1978) 35 RA knees with an observation time 3-26 months. Witvoet et al. (1974) have also published clinical results, but the patient material seems to be partly identical with the series reported by Deburge et al. (1976).

Insall et al. (1976) and Witvoet et al. (1974) reported two thirds excellent to good results. Engelbrecht et al. (1976) reported 77 % good results in 240 operations (OA + RA) with an average 33 months observation time. Lettin et al. (1978) using the Stanmore prosthesis in 100 knees (OA + RA) reported freedom from pain in 94 % and increased mobility in 67 % after more than two years.

Arden (1973) reported 80 % good results in Shier arthroplasty after more than one year. Following arthroplasty with the Walldius prosthesis, results between 67 % and 80 % were reported by Bain (1973), Freeman (1973), Walldius (1967) and Wilson and Venters (1976). Because of obvious differences in the evaluation system and population differences, a direct comparison of these results was not possible. A discrepancy obviously exists between the results in the Lund material and reported frequencies of excellent and good results. On the basis of the above clinical reports with a total of 1163 arthroplasties and the results in this material of 64, the intention was to discuss principle views of indication and complications.

Indications

The main merit of the total constrained principle is the potential for reconstructing knees with extreme deformity and instability. None of the works referred to indicated any maximum limits of destruction or instability. Arden (1973) and Engelbrecht et al. (1976) found that even ankylosed and previously arthrodesed knees could be operated with a hinge joint prosthesis if the extensor apparatus was intact. In the Lund material, the prognosis was poor when the FTP-angle preoperatively was less than 168° or attrition in FP-joints was found mainly caused by operative and postoperative FP-joint problems. The minimum indication according to Witvoët et al. (1974) and Bain (1975) was a destruction so pronounced that arthrodesis was the only alternative. Walldius (1967) found maximum invalidity equal to life in a wheel-chair the main indication. Of special interest is the minimum where other prosthetic principles were used in the same period.

three patients who regretted the operations one had an above-knee amputation, one was arthrodesed, and one had pain at rest and only 30° of flexion following surgery At follow-up, the patients opinion was

Table 33.

Almost normal	20
Improved	39
Unchanged	2
Deteriorated	3

A statistical correlation existed between the patients' opinion and the evaluation of results according to Weinfeld (Chi^2 p = 0 0005).

ARA functional classification

The ARA functional classification depends on the status of the entire locomotor system and can alter with the disease activity, therapy as well during the observation time can influence the functional grading, but it was still of interest to note whether knee arthroplasty had any nfluence

Table 34.

ARA	Preoperatively	Follow-up
II	3	10
IIIa	13	18
IIIb (risk)	24	18
IV	24	18

Improved 25
Unchanged 32
Worse 7

The improvement was significant (Wilcoxon s SRT p 0 001) which was impressing when it was taken into account that these patients on average had 1.2 other joints in the lower extremities which were painful at weight-bearing The stab lity through hinge joint arthroplasty appears to be most beneficial to the patient in activities of daily living.
There was a significant correlation between ARA functional classification and results according to We nfeld (Chi^2 p = 0 0005) However, the considerable functional gains reflected in an improvement in ARA functional classification following surgery did not result in any significant change in socio-economical conditions

DISCUSSION

Following Guépar arthroplasty in the Lund material results were "satisfactory" in 30 knees and "not satisfactory" in 34 at follow-up 2.7 years (1.0-4.3) after operation. Clinical reports of Guépar arthroplasty in mixed materials of OA and RA were published by Deburge et al. (1976) including 103 RA knees with an observation time exceeding 24 months, Insall et al. (1976) 24 RA knees with an observation time exceeding 24 months, Sneppen et al (1978) 35 RA knees with an observation time 3-26 months. Witvoet et al. (1974) have also published clinical results, but the patient material seems to be partly identical with the series reported by Deburge et al. (1976).

Insall et al (1976) and Witvoet et al. (1974) reported two thirds excellent to good results. Engelbrecht et al. (1976) reported 77 % good results in 240 operations (OA + RA) with on average 33 months observation time. Lettin et al. (1978) using the Stanmore prosthesis in 100 knees (OA + RA) reported freedom from pain in 94 % and increased mobility in 67 % after more than two years.

Arden (1973) reported 80 % good results in Shier arthroplasty after more than one year. Following arthroplasty with the Walldius prosthesis, results between 67 % and 80 % were reported by Bain (1973), Freeman (1973), Walldius (1967) and Wilson and Venters (1976). Because of obvious differences in the evaluation system and population differences, a direct comparison of these results was not possible. A discrepancy obviously exists between the results in the Lund material and reported frequencies of excellent and good results. On the basis of the above clinical reports with a total of 1163 arthroplasties and the results in this material of 64, the intention was to discuss principle views of indication and complications.

Indications

The main merit of the total constrained principle is the potential for reconstructing knees with extreme deformity and instability. None of the works referred to indicated any maximum limits of destruction or instability. Arden (1973) and Engelbrecht et al. (1976) found that even ankylosed and previously arthrodesed knees could be operated with a hinge joint prosthesis if the extensor apparatus was intact. In the Lund material, the prognosis was poor when the FTP-angle preoperatively was less than 168° or attrition in FP-joints was found mainly caused by operative and postoperative FP-joint problems. The minimum indication according to Witvoët et al. (1974) and Bain (1975) was a destruction so pronounced that arthrodesis was the only alternative. Walldius (1967) found maximum invalidity equal to life in a wheel-chair the main indication. Of special interest is the minimum indication in materials where other prosthetic principles were used in the same period.

Insall et al. (1976) reported on a material where three different unconstrained prostheses were used during the same period as the Guépar prosthesis. Here, the result following Guépar arthroplasty was better than in arthroplasties where unconstrained prostheses were used, although the destruction in the Guépar operated cases was more pronounced. They warned against using the Guépar prosthesis in younger patients because of wear on the axis of the prosthesis and on the basis of one case of fracture of the prosthesis, but did not draw any other conclusions regarding the choice between constrained and unconstrained principles. Engelbrecht et al. (1976) reported results using the St. George hinge and Schlitten surface prosthesis during the same period and on the basis of almost 900 arthroplasties recommended that hinge prosthesis should be used when extension defects or lateral malposition exceeded 20°, when considerable ligamentary destruction was present, or when mobility was less than 70°.

In the Lund material, indications were not uniform during the years when the prosthesis was used, but was always weighed against arthrodesis and against unconstrained arthroplasty. The introduction of the hemiconstrained prostheses which will probably replace the constrained hinge prosthesis has made it difficult at present to categorically state the indications for the hinge joints. On the basis of present experience, constrained or hemiconstrained prostheses should be used when the extension defect is greater than 20°, or malposition more than 20°. Probably the most important indications are subluxation of the tibia, outward rotation of the tibia and insufficiency of the cruciate ligament which prevents congruency between prosthetic components in an unconstrained arthroplasty. It is often an advantage to make the final decision during surgery when different prosthetic alternatives are possible.

Complications

An analysis of the complications and those reported in the literature illustrate the risks and drawbacks of the constrained arthroplasty.

General complications

Serious cardiopulmonary, systemic or cerebrovascular complications following hinge joint arthroplasty were reported in several series. Deburge et al. (1976) in 292 Guépar arthroplasties had 14 serious hypotensions, five with cardiac arrest; three died, lung embolism was noted in another five, postoperative respiratory insufficiency in five and serious cerebrovascular problems developed in 12. Kenesi (1978) in 758 operations reported 18 deaths in connection with the operation and in another 20 cases life-threatening cardiopulmonary complications occurred within the first 24 hours following surgery. Kenesi claimed that possible reasons for these complications were toxic reaction to

the lung parenchyma of nonpolymerized monomer, haemodynamic disturbances when releasing the bloodless field, bleeding from the operation area and fat embolism. In the Lund material, lung embolism occurred in one case and pneumonia in two but fat embolism could not be excluded Serious complications were perhaps avoided by draining the marrow cavities with a catheter when the cement was introduced and the prosthesis inserted and by good anaesthesia. Before inserting the prosthesis, Solucortef 100 mg was given i v., and the patient ventilated with pure oxygen.

D slocation of the patella

A Guépar, Stanmore, St. Georg and Walldius arthroplasty through the 'trochlea' for articulation with the patella provide a hemiarthroplasty in the FP-joint. In most published materials, FP problems have been considerable Deburge et al (1976) reported FP-joint pain in 43 of 103 Guépar arthroplasties, in 38 knees the patella was not central in relation to the trochlea of the prosthesis Insall et al (1976) found that pain was present when pressure was applied over the patella in 50 % of the cases and that alignment of the patella over the trochlea was often not achieved although lateral release was done the arthroplasty. Sneppen et al. (1978) had subluxation or total dislocation of the patella in 32 of 50 cases, but found that pain did not necessarily occur with subluxation. Engelbrecht et al (1976) stated that FP-joint pain was the most usual explanation for residual pain which was found in 18 % of the cases at follow-up, but that pain tolerance often developed after 1-2 years

FP-joint problems were considerable in the Lund material In 17 knees, the patella at surgery showed a tendency to d slocate laterally The tibial tuberosity was transferred in six knees and a lateral release and/or medial capular plication was carried out in nine. Despite this the patella dislocated later in seven knees and reoperation was necessary in three In the Lund material the frequency of dislocation increased slightly, but not significantly by increasing valgus malposition preoperatively. Lettin et al. (1978) using the Stanmore prosthesis in 80 cases had no dislocations. This can be due to the fact that the trochlea in this prosthes s is more anatomical in design and the patella is also reshaped using a template so that congruency in the femoro-patellar jo nt is achieved. In the Walldius arthroplasty (Bain 1973, Blundell-Jones 1973, Freeman 1973, Walldius 1967, Wilson and Venters 1976) the presence of FP-joint pain or dislocation was not mentioned It m ght imply that the FP-joint problem was less important when using this prosthesis If cement was not used, maximum outward rotation of the tibia was probably not often present In the Shier arthroplasty, patellectomy is necessary Arden (1973) reported rupture of the patella ligament due to attrition aga nst the prosthesis in 5 of 192 knees and other d sadvantages of patellectomy such as delayed wound healing, infection and biomechanical disadvantages must be considered The Guépar group (Alnot et al.

Insall et al. (1976) reported on a material where three different unconstrained prostheses were used during the same period as the Guépar prosthesis. Here, the result following Guépar arthroplasty was better than in arthroplasties where unconstrained prostheses were used, although the destruction in the Guépar operated cases was more pronounced. They warned against using the Guépar prosthesis in younger patients because of wear on the axis of the prosthesis and on the basis of one case of fracture of the prosthesis, but did not draw any other conclusions regarding the choice between constrained and unconstrained principles. Engelbrecht et al. (1976) reported results using the St. George hinge and Schlitten surface prosthesis during the same period and on the basis of almost 900 arthroplasties recommended that hinge prosthesis should be used when extension defects or lateral malposition exceeded 20°, when considerable ligamentary destruction was present or when mobility was less than 70°.

In the Lund material, indications were not uniform during the years when the prosthesis was used, but was always weighed against arthrodesis and against unconstrained arthroplasty. The introduction of the hemiconstrained prostheses which will probably replace the constrained hinge prosthesis has made it difficult at present to categorically state the indications for the hinge joints. On the basis of present experience, constrained or hemiconstrained prostheses should be used when the extension defect is greater than 20°, or malposition more than 20°. Probably the most important indications are subluxation of the tibia, outward rotation of the tibia and insufficiency of the cruciate ligament which prevents congruency between prosthetic components in an unconstrained arthroplasty. It is often an advantage to make the final decision during surgery when different prosthetic alternatives are possible.

Complications

An analysis of the complications and those reported in the literature illustrate the risks and drawbacks of the constrained arthroplasty.

General complications

Serious cardiopulmonary, systemic or cerebrovascular complications following hinge joint arthroplasty were reported in several series. Deburge et al. (1976) in 292 Guépar arthroplasties had 14 serious hypotensions, five with cardiac arrest; three died, lung embolism was noted in another five, postoperative respiratory insufficiency in five and serious cerebrovascular problems developed in 12. It is often an advantage to make the final decision during surgery when different prosthetic alternatives are possible.

Complications

An analysis of the complicat ons and those reported in the literature illustrate the risks and drawbacks of the constra ned arthroplasty

General complications

Serious cardiopulmonary, systemic or cerebrovascular complications following hinge joint arthroplasty were reported in several series Deburge et al (1976) in 292 Guépar arthroplasties had 14 serious hypotensions, five with cardiac arrest, three d ed, lung embolism was noted in another five, postoperative respiratory insufficiency in five and serious cerebrovascular problems developed in 12. Kenesi (1978) in 758 operations reported 18 deaths in connection with the operation and in another 20 cases life-threatening cardiopulmonary complications occurred with n the first 24 hours following surgery. Kenesi claimed that possible reasons for these complications were toxic reaction to

the lung parenchyma of nonpolymerized monomer, haemodynamic disturbances when releasing the bloodless field, bleeding from the operation area and fat embolism In the Lund material, lung embolism occurred in one case and pneumonia in two but fat embolism could not be excluded. Serious complications were perhaps avoided by draining the marrow cavities with a catheter when the cement was introduced and the prosthesis inserted and by good anaesthesia. Before inserting the prosthesis, Solucortef 100 mg was given i.v., and the patient ventilated with pure oxygen

Dislocation of the patella

A Guépar, Stanmore, St. Georg and Walldius arthroplasty through the trochlea for articulation with the patella provide a hemiarthroplasty in the FP-joint In most published materials, FP problems have been considerable: Deburge et al. (1976) reported FP-joint pain in 43 of 103 Guépar arthroplasties, in 38 knees the patella was not central in relation to the trochlea of the prosthesis. Insall et al. (1976) found that pain was present when pressure was applied over the patella in 50 % of the cases and that alignment of the patella over the "trochlea was often not achieved although lateral release was done at the arthroplasty Sneppen et al (1978) had subluxation or total dislocation of the patella in 32 of 50 cases, but found that pain did not necessarily occur with subluxation. Engelbrecht et al (1976) stated that FP-joint pain was the most usual explanation for residual pain which was found in 18 % of the cases at follow-up, but that pain tolerance often developed after 1-2 years

FP-joint problems were considerable in the Lund material In 17 knees, the patella at surgery showed a tendency to dislocate laterally The tibial tuberosity was transferred in six knees and a lateral release and/or medial capular plication was carried out in nine. Despite this the patella dislocated later in seven knees and reoperation was necessary in three In the Lund material, the frequency of dislocation increased slightly, but not significantly by increasing valgus malposition preoperatively. Lettin et al. (1978) using the Stanmore prosthesis in 80 cases had no dislocations This can be due to the fact that the trochlea in this prosthesis is more anatomical in design and the patella is also reshaped using a template so that congruency in the femoro-patellar joint is achieved. In the Walldius arthroplasty (Bain 1973, Blundell-Jones 1973, Freeman 1973, Walldius 1967, Wilson and Venters 1976) the presence of FP-joint pain or dislocation was not mentioned It might imply that the FP-joint problem was less important when using this prosthesis If cement was not used, maximum outward rotation of the tibia was probably not often present In the Shier arthroplasty, patellectomy is necessary Arden (1973) reported rupture of the patella ligament due to attrition against the prosthesis in 5 of 192 knees and other disadvantages of patellectomy such as delayed wound healing, infection and biomechanical disadvantages must be considered. The Guépar group (Alnot et al.

Insall et al. (1976) reported on a material where three different unconstrained prostheses were used during the same period as the Guépar prosthesis Here, the result following Guépar arthroplasty was better than in arthroplasties where unconstrained prostheses were used, although the destruction in the Guépar operated cases was more pronounced. They warned against using the Guépar prosthesis in younger patients because of wear on the axis of the prosthesis and on the basis of one case of fracture of the prosthesis, but did not draw any other conclusions regarding the choice between constrained and unconstrained principles. Engelbrecht et al. (1976) reported results using the St. George hinge and Schlitten surface prosthesis during the same period and on the basis of almost 900 arthroplasties recommended that hinge prosthesis should be used when extension defects or lateral malposition exceeded 20°, when considerable ligamentary destruction was present, or when mobility was less than 70°.

In the Lund material, indications were not uniform during the years when the prosthesis was used, but was always weighed against arthrodesis and against unconstrained arthroplasty. The introduction of the hemiconstrained prostheses which will probably replace the constrained hinge prosthesis has made it difficult at present to categorically state the indications for the hinge joints On the basis of present experience, constrained or hemiconstrained prostheses should be used when the extension defect is greater than 20°, or malposition more than 20°. Probably the most important indications are subluxation of the tibia, outward rotation of the tibia and insufficiency of the cruciate ligament which prevents congruency between prosthetic components in an unconstrained arthroplasty. It is often an advantage to make the final decision during surgery when different prosthetic alternatives are possible

Complications

An analysis of the complications and those reported in the literature illustrate the risks and drawbacks of the constrained arthroplasty.

General complications

Serious cardiopulmonary, system ■ or cerebrovascular complications follow ng hinge joint arthroplasty were reported in several series Deburge et al (1976) in 292 Guépar arthroplasties had 14 serious hypotensions, five with cardiac arrest, three died, lung embolism was noted in another five, postoperative respiratory insuffic ency in five and serious cerebrovascular problems developed in 12 Kenesi (1978) in 758 operat ons reported 18 deaths in connection with the operation and in another 20 cases life-threatening cardiopulmonary complications occurred within the first 24 hours following surgery Kenesi claimed that possible reasons for these complications were toxic reaction to

using Stanmore prosthesis. In the Lund material, deep infection was diagnosed in 16 knees (25 %). In one knee, the infection was noted within the first two months and in 15 knees two months to five years following surgery. A direct comparison of the reported rates might be misleading. In the Lund material, for example, the diagnosis was attained without demands for bacteriological verification.

Treatment of deep infection is extremely difficult when a cemented hinge prosthesis is used. The implant is introduced deeply into two marrow cavities and the soft tissue covering is quite thin in the knee. Resection of bone at arthroplasty and often destruction by the infection increases the problems of reconstruction. An analysis of reported deep infections, 7.5 % in approximately 1100 arthroplasties in the series previously referred to, revealed that three patients died of septicaemia, eight had above-knee amputations, in seven the prosthesis was removed and in 45 knees an arthrodesis was attempted but union occurred in only 15. The prosthesis was changed in 11 knees with a relapse in four and healing in seven. In 16 knees, the infection was treated by systemic antibiotics, in 13 the infection healed.

Loosening

Fixation of the prosthesis in bone tissue is problematic and loosening of the prosthesis with instability, deformity and pain at weight-bearing, without signs of infection was shown in most published materials with an observation period exceeding two years. Watson et al. (1976), in 38 RA knees operated with a Shier prosthesis with an observation period of two to seven years, found that pain and instability recurred within 18 months following surgery. In the same period, cystic radiolucencies and periosteal reactions were noted level with the tip of the stems as well as subsidence of the femoral component into the femur to an extent that limited flexion. These X-ray changes indicated loosening of the femoral component. Loosening with clinical symptoms were noted in 35 of 38 knees. According to Watson et al. (1976), prosthetic loosening with pain, instability and gradual decreasing mobility was unavoidable after more than 18 months following surgery. Arden (1973) reported only 7 % with loosening with an observation period exceeding 12 months in a Shier arthroplasty material of 192 knees. Following Guépar arthroplasty, Deburge et al. (1976) reported loosening in 2 % (6 cases) in 292 arthroplasties, Insall et al. (1976) in 7 % (3 cases) in 45 arthroplasties. In arthroplasty with Walldius prosthesis without the use of bone cement as recommended by Walldius (1967), Blundell-Jones (1973) reported that all prostheses were loose after two years.

The Lund material had lateral instability exceeding 10° in three knees; these had deep infection. Most of the other knees had slight (less than 5°) lateral instability, but none [illegible]rior drawer sign. None of these patients experienced instability on

1971) claimed that outward rotation of the tibia was the main reason for dislocation of the patella. Sneppen et al. (1978) claimed that damage to the vastus medialis, incorrect design of the trochlea, preoperative valgus and outward rotation of the tibia were all contributory causes. In the author's opinion the tendency to dislocation was mainly due to faulty operative technique. By introducing the axis while the bone cement in the tibia was still unpolymerized, the patella dislocated laterally and the knee flexed, a powerful outward rotation force was created on the tibia through the patellar ligament and the tibial part of the prosthesis was therefore in inward rotation in relation to the tibia itself. Lettin et al. (1978) used a lateral parapatellar incision and dislocated the patella medially, this prevented the outward rotation of the tibia.

Wound healing

The highest incidence of wound healing complications was noted by Lettin et al. (1978) in 100 Stanmore arthroplasties with delayed wound healing in 29 knees, skin necrosis in nine and a fistula in two. Arden (1973) in Shier arthroplasties found wound healing complications in 17 % of 192 cases. The required patellectomy was probably contributory. Other reports previously referred to gave lower incidences of wound healing problems. In the Lund material the wound failed to heal within four weeks in 13/64 knees despite immobilization in plaster. Transfer of the tibial tuberosity and dislocation of the patella had an adverse effect on wound healing in the distal part of the incision, corresponding to the area of the tuberosity. Deep infection later occurred in four cases.

Wound healing complications are probably partly caused by the large volume of the implant and a relatively thin soft tissue covering. They are less of a problem in unconstrained knee arthroplasty where although the approach to the joint, operation time and duration of bloodless field are the same, the implant is much smaller in size.

Deep infection

Deep infection has been reported in hinge arthroplasty in all larger series and has been extremely difficult to treat. The highest incidence of deep infection was found in Walldius' material (1967), 14 % of deep infection in 67 knees, and in Blundell-Jones material (1973), 11 % deep infections in 120 operations. The Walldius prosthesis is larger than others and was inserted without the use of bone cement which did not seem to be necessary for the high infection rates to occur. Bain (1973), Freeman (1973) and Wilson and Venters (1976), who cemented the Walldius prosthesis, reported infection rates of 5-10 %. Deburge et al. (1976) and Insall et al. (1976) both reported 7 % deep infection using the Guépar prosthesis. The lowest infection rate 2 % was reported by Engelbrecht et al. (1976) using the St. George prosthesis and Lettin et al. (1978), 3 %

using Stanmore prosthesis. In the Lund material, deep infection was diagnosed in 16 knees (25 %) In one knee, the infection was noted within the first two months and in 15 knees two months to five years following surgery A direct comparison of the reported rates might be m sleading In the Lund material, for example, the diagnosis was attained without demands for bacteriological verification

Treatment of deep infection is extremely difficult when a cemented hinge prosthesis is used The implant is introduced deeply into two marrow cavities and the soft tissue covering is quite thin in the knee Resection of bone at arthroplasty and often destruction by the infection increases the problems of reconstruction An analysis of reported deep infections, 7 5 % in approximately 1100 arthroplasties in the series previously referred to revealed that three patients died of septicoemia, eight had above-knee amputations, in seven the prosthesis was removed and in 45 knees an arthrodesis was attempted but union occurred in only 15 The prosthesis was changed in 11 knees with a relapse in four and healing in seven In 16 knees, the infection was treated by systemic antibiotics, in 13 the infection healed

Loosening

Fixat on of the prosthesis in bone tissue is problematic and loosening of the prosthesis with instabil ty deformity and pa n at weight-bearing without signs of infection was shown in most published materials with an observation period exceeding two years Watson et al (1976), in 38 RA knees operated with a Shier prosthesis with an observat on period of two to seven years found that pain and instability recurred within 18 months following surgery In the same period, cystic radiolucencies and periosteal react ons were noted level with the tip of the stems as well as subs dence of the femoral component into the femur to an extent that l mited flexion These X-ray changes indicated loosen ng of the femoral component Loosening with clinical symptoms were noted in 35 of 38 knees According to Watson et al (1976), prosthetic loosening with pa n, instabil ty and gradual decreasing mobility was unavo dable after more than 18 months following surgery Arden (1973) reported only 7 % with loosening with an observation period exceed ng 12 months n a Sh er arthroplasty material of 192 knees. Following Guépar arthroplasty Deburge et al (1976) reported loosening in 2 % (6 cases) in 292 arthroplasties Insall et al (1976) in 7 % (3 cases) in 45 arthroplasties In arthroplasty with Walld us prosthes s without the use of bone cement as recommended by Walldius (1967), Blundell-Jones (1973) reported that all prostheses were loose after two years.

The Lund material had lateral instab lity exceed ng 10° in three knees, these had deep nfection Most of the other knees had slight (less than 5°) lateral instab lity, but none of them had an anterior drawer s gn None of these patients experienced instability on

1971) claimed that outward rotation of the tibia was the main reason for dislocation of the patella. Sneppen et al. (1978) claimed that damage to the vastus medialis, incorrect design of the trochlea , preoperative valgus and outward rotation of the tibia were all contributory causes In the author s opinion the tendency to dislocation was mainly due to faulty operative technique. Loosening

Fixation of the prosthesis in bone tissue is problematic and loosening of the prosthesis with instability, deformity and pain at weight-bearing, without signs of infection was shown in most published materials with an observation period exceeding two years. Watson et al (1976), in 38 RA knees operated with a Shier prosthesis with an observation period of two to seven years, found that pain and instability recurred within 18 months following surgery In the same period, cystic radiolucencies and periosteal reactions were noted level with the tip of the stems as well as subsidence of the femoral component into the femur to an extent that limited flexion These X-ray changes indicated loosening of the femoral component Loosening with clinical symptoms were noted in 35 of 38 knees According to Watson et al (1976), prosthetic loosening with pain, instability and gradual decreasing mobility was unavoidable after more than 18 months following surgery Arden (1973) reported only 7 % with loosening with an observation period exceeding 12 months in a Shier arthroplasty material of 192 knees. Following Guépar arthroplasty, Deburge et al (1976) reported loosening in 2 % (6 cases) in 292 arthroplasties Insall et al (1976) in 7 % (3 cases) in 45 arthroplasties. In arthroplasty with Walldius prosthesis without the use of bone cement as recommended by Walldius (1967), Blundell-Jones (1973) reported that all prostheses were loose after two years.

The Lund material had lateral instability exceeding 10° in three knees, these had deep infection. Most of the other knees had slight (less than 5°) lateral instability, but none of them had an anterior drawer sign. None of these patients experienced instability on

walking. The slight lateral instability was taken to indicate that rigid fixation of the prosthesis and cement to the bone tissue in one or both diaphyses was not maintained in most cases after two years. In the same period when this slight instability developed, a significant decrease of the quadriceps power was noted. On forceful contraction of the quadriceps, most patients experienced an intensive, deep pain. The weakening of the quadriceps power was considered to be caused by pain inhibition; perhaps pain was caused by compression of granulation tissue in the space between cement and bone. In the Lund material aseptic loosening was of quite limited consequence and the instability was without practical importance. The effect of quadriceps weakening was difficult to judge; patients with hinge joint prostheses do not usually flex much in the stand-phase during walking and the demands on quadriceps power therefore are less than normal (van Hussen 1973). Adequate fixation of the prosthesis at operation appeared important. The Lund material had a significantly increased frequency of a radiolucent zone larger than 1 mm after one year when one or both prosthetic stems were not properly surrounded by cement. Also Insall et al. (1976) noted a slight instability following Guépar arthroplasty, and explained it as being caused by wear of the axle in the prosthesis. Mazas et al. (1973) reported on wear of the prosthesis in vitro and by simple trigonometric calculations on the basis of these values, it does not seem probable that wear of the axle contributes to the lateral instability to any great extent. Removal of the prosthesis after several years of function in active patients revealed only negligible wear of the axle.

SUMMARY

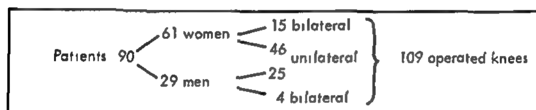
64 knees in 49 patients with RA were operated with the Guépar prosthesis from 1972 through 1976. At follow-up 2.7 years after operation, an arbitrarily chosen degree of normalization of the knee, 0-6 points according to Weinfeld's evaluation system equal to a "satisfactory" result, was attained in 30 of 64 operated knees. Of 34 knees with a "not satisfactory" result, an improvement was noted in 31, unchanged in two and worse in one. Arthroplasty resulted in reduction of pain, of need for support in walking, of extension defect, of lateral instability and of the deformity at weight-bearing. Quadriceps power was improved. Flexion was not significantly diminished. 59 knees were judged by the patients to be improved and five knees were unchanged or worse. A significant improvement in ARA functional classification occurred.

No serious general complication in relation to the operation was noted. Considerable operative and postoperative FP joint problems were found, especially following preoperative valgus. The result was significantly worse when dislocation of the patella existed. Following perforation of the femoral or the tibial diaphyses at surgery, the result was

"not satisfactory'. Although immobilized in plaster for two weeks postoperatively, there was delayed wound healing in 13 knees and four of them developed late infection.

Late infection developed in 15 knees. Infected cases were reviewed, on average, 4.6 years after operation, they were followed after the end of the general observation period. As a consequence of infection, two patients died of septicaemia and one had an above-knee amputation Five knees were reoperated, four with a change of prosthesis and one arthrodesis At follow-up, the result was 'satisfactory in only three with late infection.

Mechanical loosening of the prosthesis with slight lateral instability and reduction of quadriceps power was noted at follow-up when the observation period exceeded two years in most of the cases, but did not affect the result of the arthroplasty.



The main merit of the constrained principle is the almost unlimited capacity for correcting deformities and instability But a high frequency of patella dislocation, complicated wound healing, and late infection strongly argues against use of the method unless improvements in technique and infection prophylaxis are developed. Dislocation of the patella can probably generally be prevented if outward rotation of the tibia is prevented by cementing in the tibial component before fixating the femoral component. A reduced frequency of dislocation of the patella could also result in a lower frequency of delayed wound healing A reduction of the frequency of late infections could probably be achieved by improved hygiene and prophylactic antibiotics. Since the introduction of a number of hemiconstrained prostheses, the use of hinge joint prostheses can probably be restricted but observation periods thus far have been too short to establish rational indications.

V. MARMOR ARTHROPLASTY

MATERIAL AND METHODS

With the intention of evaluationg as early as possible the results following Marmor arthroplasty, a preliminary examination was made approximately 12 months after operation During 1977-1978, a second follow-up was made of all arthroplasties at least six months after the preliminary examination. In this way, 96 knees were examined on two occasions with, on average, 15 months (6-32) between them from 1974 through 1977. Marmor arthroplasty was performed in 90 patients with RA in 61 women and 29 men, 4 men and 15 women were operated bilaterally making a total of 109 knees.
Dem arthroplasty was performed in nine knees (5 lateral, 4 medial)

Fig. 21.

All operated knees were examined by the author and are included in the material.

The observation time averaged 2 2 years (1.0-3.6). One knee included in this series was reoperated with a Guépar arthroplasty one month following surgery because of collapse of the med al compartment

Average age at operation was 59 years (24-79) with identical sex distribution

Most patients had had rheumatoid arthritis for more than 10 years before the arthroplasty. Three-fourths of the knees were symptomatic for more than five years

Table 35.
ESR preoperatively

ESR mm/h	0-25	26-65	66-150
Knees	13	58	38

Previous treatment of the operated knee

Intra-articular cortisone. In 56 knees 1–10 cortisone injections were given and in 37 knees more than 10 injections. 16 knees were never treated with intra-articular cortisone.

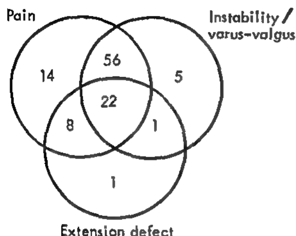
Synovectomy. Chemical synovectomy using osmium acid was carried out in 12 knees and a combination of chemical and surgical synovectomy in 29 knees. Surgical synovectomy alone was performed in 18 knees making a total of 59 chemical and/or surgical synovectom es.

Capsulotomy was performed in three knees for correction of a flexion contracture.

High tibial osteotomy was carried out in three knees, two for correction of an extension defect and one for correction of an extension defect combined with valgus malposition.

McIntosh arthroplasty. Seven previous McIntosh arthroplasties were converted to Marmor arthroplasties

Indications for operations



Ind cations in this material were not uniform. In 1974, the Marmor prosthesis was used as an alternative to Guépar arthroplasty when the pathological changes were not too advanced In 1975 and 1976, the indications were widened to include also those knees with severe destruction because of an unacceptably high incidence of deep infections following Guépar arthroplasty In retrospect it is obvious that the indications for the Marmor arthroplasty at that period were in some cases unrealistic.

After introduction of the Attenborough prosthesis in 1977, the Marmor prosthesis could again be reserved for knees requiring resurfacing and where deformities were correctible within the potentials of the prosthetic design.

Fig. 22.

Clinical indications for Marmor arthroplasty in 107 knees.

See Fig. 4 for definition of subsets.

Pain was present in 100 knees. Of them, extension defects exceeding 15° were found in 30 and instability and/or malposition ≥10° in 78. In seven without pain preoperatively, the indication for operation was an extension defect and/or malposition. Decreased flexion was in no instance of major importance as an indication for surgery.

Contraindications

Synovectomy was preferred if joint surfaces were congruent, the deformity was moderate and the patient younger than 60 years. In 1974 and 1975, the Guépar prosthesis was preferred if varus or valgus malposition or extension defect exceeded 20°. Lateral subluxation of the tibia and pronounced outward rotation of the tibia which could not be corrected were relative contraindications.

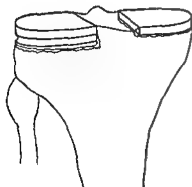


Fig. 23. The medial prosthesis is countersunk in a trough according to the original technique. The lateral prosthesis is placed with circumferential cortical support.

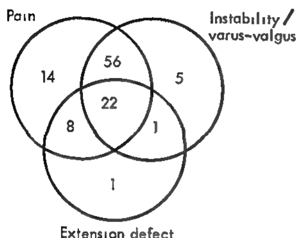
Operative technique

Two surgeons operated two thirds of the knees and seven surgeons operated 1-15 knees each. The operation was performed in a bloodless field under general or epidural anaesthesia. A medial parapatellar incision was used and the patella was dislocated laterally. A synovectomy was performed. Resection of the posterior fifth of the femoral condyles allowed for the tibia plateaux to be chiselled at right angles to the longitudinal axis of the tibia. In Marmor s (1973) description of the technique, the tibial plates are placed within corticalis, but we have considered it an advantage to have circumferential cortical support for the prosthesis (Fig. 23) The position of the femoral prosthesis was determined by the need for congruency in relation to the tibial components and the need for sufficient support (Fig 24a and b) Prominence of the anterior part of the femoral component was when possible avoided because this might cause impingement on the patella during flexion (Fig. 25a and b). The size of the femoral component was decided by the configuration of the condyle. Before closure of the joint capsule it was ensured that the patella did not impinge on the anterior edge of the femoral components. In this series patellectomy was performed in 12 knees for this reason After patellectomy, mobilization was more difficult and in most cases persistant weakness of the quadriceps resulted. A long-leg compression bandage was applied and vacuum drainage was maintained for 24-48 hours

Antibiotics : Cloxacillin 1 g x 4 and probenecid 1 g x 2 was started before surgery and continued postoperatively for 10 days in 86 knees. In 23 knees no antibiotics were given before surgery or were discontinued earlier than 10 days because of secondary effects.

Anticoagulation therapy was not used routinely

Postoperative treatment



Quadriceps exercise started from the first postoperative day and as soon as the leg could be elevated against gravity, weight-bearing with crutches was allowed

COMPLICATIONS

Operative complications and technical difficulties

In 66 of 109 operations, no technical difficulties or complications were encountered. In 43 operations, the technique was modified or complications were noted. Two complications were noted in 15 operations

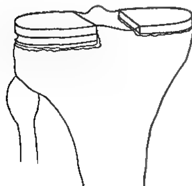


Fig. 22.

fter cementing in seven knees. In six knees recementing was done, in one the insufficient anchorage was accepted. In three knees one of the tibial components was anchored in an unplanned inclination due to dislocation under the polymerization phase.

Others. In two knees extreme osteoporosis was found at operation. Partial rupture of the patellar ligament while everting and laterally dislocating the patella occurred in one knee. *The rupture was repaired.*

Postoperative complications

In six operations *general complications were noted* and local complications in 35.

General complications. At operation, cardiac arrhythmia occurred in one case and subendocardial infarction in two cases. Within the first postoperative week, one pneumonia, one Addison crisis in a cortisone treated patient and a deep vein thrombosis in the operated extremity were diagnosed. In all cases of general complications, the patients recovered without sequelae on conventional therapy. No cases of embolism were detected. No patient died as a result of the operation or during the hospital stay.

Complicated wound healing – superficial infection. In 11 knees the wound failed to heal within four weeks; culture was negative in 10. The reason for delayed wound healing in five knees was skin necrosis, which healed spontaneously in two and in three necessitated surgical intervention. In four knees, serous secretion was found which dried up spontaneously within three months. Antibiotics were given in all knees with delayed wound healing but in no case was this prolonged more than six months. Total wound rupture four days after operation occurred when one patient fell and hyperflexed the knee. The wound was resutured after irrigation with antibiotics and healed uneventfully. In one knee purulent secretion from the wound was found four weeks after operation and culture showed staph. albus. Revision was done at which a fragment of bone cement was found in the subcutaneous tissue. The wound healed after resuturing, but the knee was warm *and tender and antibiotics were continued for six months.*

A slightly increased incidence of patellectomy and high incidence of previous operations in the involved knee were found when wound healing was complicated. Systemic treatment with cortisone seemed not to be of importance. The hospital stay was only increased by 1.7 days on an average when complicated wound healing was present.

FP-joint pain. In five knees there was pain and crepitation at the FP-joint. Patellectomy was done in one and the knee became painfree, but because of an extension defect, quadriceps insufficiency and instability, an arthrodesis was later performed. In the other four knees, the pain spontaneously diminished.

Fracture of the tibia – resection of the tibial spine. In five operations, the tibial spine was fractured, in three other operations, the spine was chiselled away because of collision against the anterior rim of the intercondyloid fossa. In these eight knees, the insertion and thereby the function of the anterior cruciate ligament was destroyed

Fracture of the femur. In one knee with pronounced rotatory instability, the medial femoral component was entrapped during flexion postero-medially against the tibial condyle. During reduction the medial femoral condyle was fractured. The fracture was retained in position by wire and healed uneventfully, although mobilization was long and troublesome.

Cysts in the femur or tibia. In seven knees large cysts were found subchondrally in the femoral or tibial condyles, necessitating larger resections or the filling of defects with cement.

Impingement of the patella. In 15 knees, impingement of the patella against the anterior edge of one or both femoral components occurred at operation. This was caused by prominence of the femoral component in the patella sulcus and was often combined with a pathologically altered patella In 12 knees, a patellectomy was performed but in three the impingement was accepted with the expectation that the patella would be worn so that congruency would develop. An extension defect was found at follow-up in 5 of 15 knees against 22 of 94 knees without FP-joint problems at operation. The difference was not significant. However, the quadriceps power was significantly reduced after patellectomy.

Extension defect. In seven knees with an extension defect between 15-35° preoperatively, the tibial plates were anteriorly inclined. In four of these there was an extension defect exceeding 10° at follow-up

Congruence problems. In seven knees, the surgeon considered the relationship between the tibial and femoral components as not being satisfactory, in five the tib a later subluxated laterally or posteriorly in relation to the femur, resulting in collapse of the arthroplasty. Reoperation with an Attenborough prosthesis was performed in three knees and with a Guépar prosthes s in one Reoperation was planned in another

Insufficient correction of malposition. Deformity in valgus was accepted in three knees to achieve lateral stability and full extension.

Cementation problems. One or both tibial components were found insufficiently anchored

after cementing in seven knees. In six knees *recementing* was done, in one the insufficient anchorage was accepted. In three knees one of the tibial components was anchored in an unplanned inclination due to dislocation under the polymerization phase.

Others. In two knees extreme osteoporosis was found at operation. Partial rupture of the patellar ligament while everting and laterally dislocating the patella occurred in one knee. *The rupture was repaired.*

Postoperative complications

In six operations *general complications were noted* and local complications in 35.

General complications. At operation, cardiac arrhythmia occurred in one case and subendocardial infarction in two cases. Within the first postoperative week, one pneumonia, *one Addison crisis in a cortisone treated patient* and a deep vein thrombosis in the operated extremity were diagnosed. In all cases of general complications, the patients recovered without sequelae on conventional therapy. No cases of embolism were detected. No patient died as a result of the operation or during the hospital stay.

Complicated wound healing - superficial infection. In 11 knees the wound failed to heal within four weeks, culture was negative in 10. The reason for delayed wound healing in five knees was skin necrosis, which healed spontaneously in two and in three necessitated surgical intervention. In four knees, serous secretion was found which dried up spontaneously within three months. Antibiotics were given in all knees with delayed wound healing but in no case was this prolonged more than six months. Total wound rupture four days after operation occurred when one patient fell and hyperflexed the knee. The wound was resutured after irrigation with antibiotics and healed uneventfully. In one knee purulent secretion from the wound was found four weeks after operation and culture showed staph albus. Revision was done at which a fragment of bone cement was found in the subcutaneous tissue. The wound healed after resuturing, but the knee was warm and tender and antibiotics were continued for six months.

A slightly increased incidence of patellectomy and high incidence of previous operations in the involved knee were found when wound healing was complicated. Systemic treatment with cortisone seemed not to be of importance. The hospital stay was only increased by 1.7 days on on average when complicated wound healing was present.

FP-joint pain. In five knees there was pain and crepitation at the FP-joint. Patellectomy was done in one and the knee became painfree, but because of an extension defect, quadriceps insufficiency and instability, an arthrodesis was later performed. In the other four knees, the pain spontaneously diminished.

Dislocation of prosthesis. In one knee with persistent pain at weight-bearing, the joint was explored one month after operation and one of the femoral components was found loosened. After recementing, the knee became painfree. In the first month after operation, an increasing varus malposition was recognized in one knee associated with increasing pain at weight-bearing. X-ray examination showed an increasing collapse of the medial compartment with loosening and dislocation of the tibial prosthesis. A Guépar arthroplasty was performed.

Peroneal palsy developed after seven operations. At follow-up, a partial anaesthesia on the dorsum of the foot was found in one patient; six were fully recovered.

Fracture. One patient fell at home one month after arthroplasty and fractured the medial femoral condyle. The fracture healed after eight weeks immobilization in a static orthosis.

Others. In four knees where patellectomy was performed in conjunction with the arthroplasty, an extension lag of 15-40° was found, in two of them the quadriceps power remained less than 50N at follow-up. One knee had painful crepitation, which did not arise from the FP-joint. A cineradiography showed that a collision between the lateral femoral prosthesis and the eminentia occurred during flexion. This phenomenon seemed to be caused by a moderate lateralization of the tibia and was probably accentuated by a weakness of the quadriceps, which was secondary to an earlier patellectomy. During physiotherapy, one knee suddenly locked in 90° of flexion. At aspiration 50 ml serous sanguinous fluid were removed. The locking has not recurred. One knee had continuous moderate bleeding from the wound for two weeks, although coagulation tests were normal. One 68-year-old cortisone-treated patient developed a postoperative haematoma in the thigh in the area where the bloodless field was applied. The haematoma resorbed spontaneously but the quadriceps power remained extremely reduced. During physiotherapy two weeks after operation, one patient fainted and fell, probably due to a subendocardial infarct and sustained a cervical hip fracture. Because of necrosis of the head of the femur after primary nailing, a Moore arthroplasty was later performed.

Hospital stay. The average stay in hospital in the Orthopaedic or Rheumatological Department was 34 days (7-119).

Late complications

16 late complications were noted in 15 knees.

Dislocation of prosthesis. One knee was explc

pain at weight-bearing. A cineradiographic examination was made before reoperation. This showed a mobile femoral component, which was recemented, and the knee became painfree. Six knees had a dislocation of one or both tibial components within the first postoperative year. At arthroplasty, congruency between the tibial and femoral components was not achieved in this group. All these knees were reoperated, one had an arthrodesis, one ■ Guépar, and four an Attenborough.

Collapse of condyles. Because of pain at weight-bearing and increasing instability caused by destruction of the non-operated compartment following demi-arthroplasties, completion with ■ prosthesis in the lateral compartment was done in two knees and in the medial compartment in one. Pain at weight-bearing was found in ■ further two knees, which have not been reoperated.

Fractures. One patient fell at home one year after the arthroplasty sustaining a supracondylar femur fracture with minimum dislocation. Reoperation with recementation of a dislocated medial tibial plate was planned when the fracture occurred, but the patient preferred an arthrodesis

One patient noted pain at weight-bearing localized at the medial compartment. Several roentgen examinations did not show anything abnormal. Scintimetry with Sr^{85} six months after operation showed increased activity in the medial tibial condyle. During the following months, callus could be seen in the medial condyle on roentgen, and the patient became painfree simultaneously with normalization of the scintimetry. This knee illustrates the d fficulties of diagnosing stress fractures in patients with rheumatoid arthritis

Hospital stay. The average stay in hospital in the Orthopaedic or Rheumatological Department was 34 days (7-119).

Late complications

16 late complications were noted in 15 knees.

Dislocation of prosthesis. One knee was explored six months after operation because of

From the patients' point of view, pain was the *main indication* for operation. In this material, pain was an important indication in 101 of 109 operations. *In* 88 knees pain was eliminated or less severe at follow-up than preoperatively, unchanged in 17 and more severe in four. In five knees with pain at weight-bearing or at rest, reoperation with another prosthesis was done or was planned after the end of the observation time. From the preliminary examination to follow-up, pain diminished in 22 knees and increased in 12. *In 28 knees with pain at walking less than 200 m at follow-up significant* correlation was found in presence of exudate, anterior drawer sign, lateral instability, weakness of the quadriceps, and pain at weight-bearing in at least three other joints.

Pain at rest or immediately at weight-bearing was found in 18 knees at follow-up. An analysis of operative technical difficulties and the complications postoperatively, during the observation time and the clinical status at follow-up showed that the main cause of pain was most probably the following

Dislocation of tibial component	6 knees
Incongruency between prosthetic components	4 knees
Instability (anterior drawer sign + lateral instability)	3 knees
FP-joint dysfunction	3 knees
Extension lag + quadriceps-insufficiency	2 knees

Table 37

Use of *support at walking*.

Preop. points	Follow-up 0 (44)	1 (21)	2 (25)	4 (19)	Sum
4	23	7	12	13	55
2	6	7	6	1	20
1	5	4	1	1	11
0	10	3	6	4	23

In 60 knees the need for support at walking was reduced, unchanged in 33, and increased in 16. From the preliminary examination to follow-up (on *average* 15 *months*), the need for support at walking was reduced in 16 knees and increased *in* 22. *At* quadriceps power less than 150N, the need for support at walking was *significantly* increased. The need for support at walking was significantly increased *when an extension defect was* present.

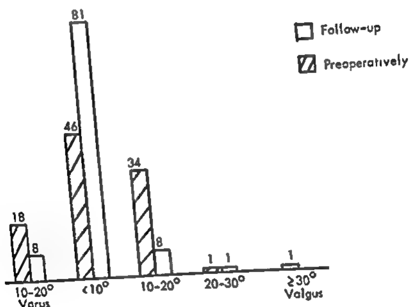
Fig. 25a. Impingement of patella on anterior edge of the femoral component• wear defect of patella.

Fig. 25b. Same case axial exposure of the FP-joint wear defect of patella.

Others. In two knees, loose fragments of cement were identified by roentgen examination, apparently without major clinical symptoms.

Late infection. Late infection occurred in two knees (2 %). In one of these the infection was multifocal, due to septicaemia.

FOLLOW-UP EVALUATION



The seven parameters in Weinfeld's evaluation system (see page 9) formed the basis for the evaluation of status preoperatively and at follow-up.

Table 36.
Pain.

Preop. (points) \ Follow-up (points)	0	1	3	6	7	Sum
7	41	2	6	5	5	59
6	23	3	3	6	1	36
3	3	1	1		1	6
1	1					1
0	5	2				7
Follow-up sum	73	8	10	11	7	

Preoperative instability was eliminated in 39 of 94 knees and reduced in four. In nine knees instability developed in preoperatively stable knees, in three it increased. At follow-up, instability >10° was found in 41 knees. From the preliminary examination to follow-up instability was significantly increased. A high incidence of loosening of the prosthesis and altered position could explain this development. The importance of medial or lateral instability might be increased by being found correlated to the presence of an anterior drawer sign (Chi^2 p 0.0001).

Fig. 26.
Varus-valgus at weight-bearing (clinical).

Preoperatively 18 knees had a varus malposition of more than 10°. 13 were correcte but in three previously normal knees, a varus malposition developed. Of 35 knees w a valgus malposition ≥10° preoperatively, correction was achieved in 25, reductior one and increased valgus malposition developed in three knees. There was a signific correlation between the degree of varus and valgus malposition and the degree of c lage reduction and bone attrition noted at operation. From the preliminary examina to follow-up, a reduction of malposition was found in five knees and an increase ir

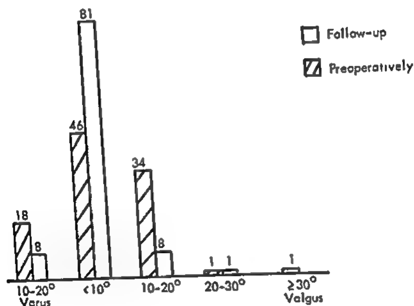
Table 38.
Extension defect.

Preop. (points)	Follow-up 0	Follow-up 1	Follow-up 2	Follow-up 4	Sum
Follow-up sum	82	22	5		
4	2	1	1		4
2	16	9	4		29
1	36	11	0		47
0	28	1	0		29

A preoperative extension defect was corrected by arthroplasty in 54 of 80 knees, reduced in a further 11 knees, unchanged in 43 and increased in one. From the preliminary examination to follow-up, it was eliminated in 10, reduced in two, developed in 10 and increased in three.

Table 39.
Flexion.

Preop. (points)	Follow-up 0	Follow-up 1	Follow-up 3	Sum
Follow-up sum	104	4	1	
3		1		1
1	4			4
0	100	3	1	104



Flexion less than 80° was found preoperatively in five knees and at follow-up of these flexion exceeding 80° was found in four and an improvement in one. In five knees, flexion less than 80° was found at follow-up. From the preliminary examination to follow-up, flexion increased in seven knees and was reduced in two.

Table 40.
Medial or lateral instability.

Preop. (points)	Follow-up 0	Follow-up 2	Follow-up 4	Sum
Follow-up sum	59	36	5	
4	1	4	1	6
2	38	24	3	65
0	20	8	1	29

reoperative instability was eliminated in 39 of 94 knees and reduced in four. In nine nees instability developed in preoperatively stable knees, in three it increased. At ollow-up, instability $>10^{\circ}$ was found in 41 knees. From the preliminary examination to ollow-up instability was significantly increased. A high incidence of loosening of the rosthesis and altered position could explain this development. The importance of medial or lateral instability might be increased by being found correlated to the presence of an anterior drawer sign (Chi^2 p 0.0001).

Fig. 26.
Varus-valgus at weight-bearing (clinical).

Preoperatively 18 knees had a varus malposition of more than 10°. 13 were corrected, but in three previously normal knees, a varus malposition developed. Of 35 knees with a valgus malposition $\geq 10^{\circ}$ preoperatively, correction was achieved in 25, reduction in one and increased valgus malposition developed in three knees. There was a significant correlation between the degree of varus and valgus malposition and the degree of cartilage reduction and bone attrition noted at operation. From the preliminary examination to follow-up, a reduction of malposition was found in five knees and an increase in 12.

Table 41.

Quadriceps power.

	Follow-up 25	17	18	13	Sum	
4	10	9	13	9	41	
2	11	6	4	3	24	Preop.
1						
0	4	2	1	1	8	
Points	0	1	2	4		

The quadriceps power was improved in 49 knees, unchanged in 17 and reduced in seven. From the preliminary examination to follow-up, an improvement was found in 18 knees and a deterioration in 27. No correlation was found between quadriceps power and passive mobility or crepitation of the patella.

Conclusion of results according to Weinfeld

For each of the seven parameters, the average point score preoperatively and at follow-up was calculated on the basis of the number of observations.

Table 42.

Score according to Weinfeld for the Marmor material preoperatively at the preliminary examination and at follow-up.

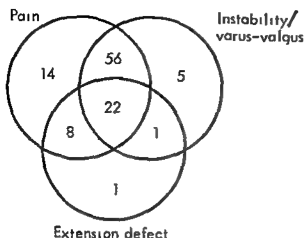
	Pre-operatively	Preliminary examination (12 months after operation)	Follow-up	Number of observations	Significant improvement (p)x)
Pain (0-7 points)	5.9	1.5	1.4	109	<0.001
Use of support at walking (0-4 points)	2.5	1.2	1.2	109	<0.0001
Extension defect (0-4 points)	1.1	0.3	0.3	109	<0.001
Flexion (0-6 points)	0.1	0.1	0.1	109	0.425
Medial or lateral instability (0-4 points)	1.5	0.5	0.9	100	<0.0001
Varus-valgus at weight-bearing (0-4 points)	1.1	0.2	0.4	99	0.015
Quadriceps power (0-4 points)	3.2	1.3	1.4	63	<0.001
Sum demerit points	15.3	5.1	5.7		

Improved: 9.6 points (63 %)

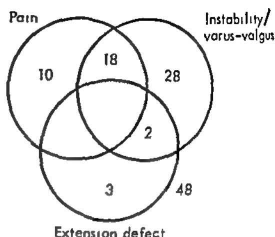
x) *From preoperative to follow-up status.*

The average demerit points preoperatively was 15.3 against 5 7 at follow-up. The score was thus reduced by 9 6 points (63 %) From the preliminary examination to follow-up 15 months later, the average score according to Weinfeld was increased by 0.6 points. The mo n reason for this deterioration was an increased incidence of lateral instability caused by loosening of the tibial components. On the basis of a comparison between the average po nts for the seven parameters included in the evaluation system preoperatively and at follow-up, it was found that with the Marmor arthroplasty there was a significant reduction of pa n, of use of support at walking, of extension defect, of lateral instability, of varus and valgus deformity and of weakness of quadriceps. Flexion was not significantly changed

In classing the knees at follow-up according to score based on Weinfeld s evaluation system 31 were excellent, 45 good, 13 fair, and 20 poor. By simplifying the system to include only two groups to facilitate the statistical analysis of the material, 76 knees were satisfactory (0-6 points) and 33 not satisfactory (7-33 points)



When comparing the status preoperatively and at follow-up for the individual knee, excluding parameters that cannot be correlated because of inadequate data (quadriceps power preoperatively in 36 knees), it was found that, of the 33 knees with a "not satisfactory" result, 21 were improved, 2 unchanged, and 10 worse Dislocation of the prosthesis was responsible in 6 of the 10 knees that were worse In the patients opinion, an improvement was found in 17 knees, 7 were unchanged, and 9 had deteriorated.



Clinical ind cat ons for operation and results at follow-up

Cl n cal indications for operation were compared with s m lar parameters in Venn diagrams to illustrate the effect of arthroplasty

Fig. 27.

See Fig. 4 for definition of subsets.

Preoperatively, all knees were in the diagram with 22 knees in the central subset. At follow-up, 48 knees were removed from the diagram and none remained in the central subset.

EFFECT OF COMPLICATIONS ON FINAL RESULTS

(Satisfactory implies a Weinfeld score 0-6)

	No. of knees	Satisfactory	Not satisfactory
Operative complications (knees)	43	18	25
Accidental loosening of anterior cruciate lig.	8	3	5
Fracture medial femoral condyle	1	1	-
Tibial cysts	7	5	2
Impingement of patella on femur component	15	10	5
Anterior inclination of tibial component	7	3	4
Incongruency	7	2	5
Lateral malposition not corrected	3	2	1
Insufficient cement initially	7	3	4
Osteoporosis	2	1	1
Patella ligament rupture	1	1	-
No. of complications (2 complications were noted in 15 operations)	58		

	No. of knees	Satisfactory	Not satis-factory
ostoperative complications (within two onths)	35	28	7
omplicated wound healing	11	6	5
Patella impingement	5	4	1
Dislocation femoral component	1	1	-
Dislocation tibial component	1	-	1

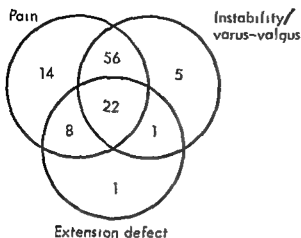
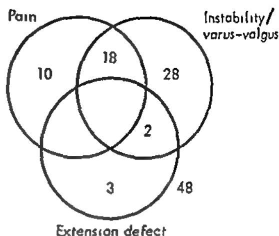
Loose fragments of cement	2	2	-
Condylar fractures	2	1	1
No. of complications (2 complications were noted in one knee)	16		
Without complications	37	29	8



PREOPERATIVE ROENTGEN FINDINGS RELATED TO RESULTS



Narrowing of the articular space was found in six knees, obliteration in 19 and attrition of FT-joints in 67. The articular space exceeded 3 mm in the best compartment in only 10 knees. When attrit on in one or both compartments was present, a significant increase in the FTP-angle difference in provocation in varus and valgus was found (Chi^2 p = 0.015). In 13 knees attrition was combined with subluxation of tibia in relation to femur. Results at follow-up were not related to the degree of observed destruction in the FT-joints.

Reduction of cartilage and attrition in FP-joints, FTP-angle at varus and valgus provocation and FTP-angle difference at varus and valgus provocation were evaluated after same methods as in the McIntosh material but were found without prognostic value.

Change in position of the prosthesis in relation to prosthesis loosening

In the lateral compartment, a change in the position of the tibial component exceeding 5° was found in 24 knees, and in the medial compartment, in 33 cases (Fig. 30). A significant correlation between loosening of prosthesis and change in position was found in the medial compartment (Chi^2 0 012) and in the lateral compartment (Chi^2 p = 0.0358). Treatment with systemic cortisone for more than one year and the length and weight of the patient had no influence on the incidence of change in position of the prosthesis.

Radiolucent zone beneath the tibial prosthesis

In 11 knees where the zone exceeded 2 mm beneath one of the components, the result was "satisfactory in five knees (Fig 32) With increasing width of the zone there was a significant increased incidence of changed position of the prosthesis in the medial (Chi^2 p - 0 009) and lateral compartment (Chi^2 p = 0.022). This confirmed the supposition that the development of a radiological zone reflects mobility between bone and cement.

Fig 28 Lateral subluxation of tibia, eminent a collision of lateral femoral component, dislocation of medial femoral component.

ROENTGEN EXAMINATION AND RESULTS AT FOLLOW-UP

The findings at the roentgen examination will be published in a separate paper (Andersen et al., unpublished data) and only results of relevance to the discussion in this chapter will be presented here.

FTP-angle at varus and valgus provocation and FTP-angle difference at varus and valgus provocation were found without significant influence on the results at follow-up.

Position of tibial components at follow-up

The usual malposition on a frontal view were medial inclination of the tibial components. Malpositions were more usual in the medial compartment than in the lateral. On the lateral view, the usual malposition was posterior inclination.

Loosening of tibial components

The indicator wire is placed in direct contact with bone cement which anchors the component to the bone. A break and/or buckling of the indicator wire is therefore a sign of loosening of the prosthesis (Fig. 29).

Table 43.

Thickness of components	Lateral component		Medial component	
	Stable	Loose	Stable	Loose
6 mm	9	10	17	23
9 mm	31	8	24	5
12 mm	16	2	9	2
15 mm-21 mm	7	1	1	3

(Inadequate data 22)

The indicator wire was broken in seven knees and buckled in 21. Breakage and buckling were combined in a further 26 knees. In 21 knees, the lateral prosthesis was loose and in 33, the medial prosthesis. The difference in frequency of loosening of medial and lateral components was significant (Chi^2 $p = 0.018$). In the medial compartment, a 6 mm thick prosthesis was used in 40 knees. Of these, 23 were loose. It was more usual to use a 6 mm thick prosthesis in the medial compartment than in the lateral and the higher incidence of loosening in the medial compartment could partly be explained by this.

Fig. 32. Radiolucent zone 2 mm wide below lateral tibial component in a case with late infection. No signs of loosening between component and cement.

Summary of major pathological roentgen findings at follow-up

At operation, the technical aim was to achieve a normal FT-angle, positioning of the tibial components without major inclination, stable anchorage of all components and central articulation of the femoral and tibial components.

A Venn diagram indicates the correlation of major pathological findings at follow-up (Fig 3 Percentage of pathological findings are calculated in Table 44

There were no abnormal findings at the X-ray examination at follow-up in 20 knees, at follow-up the result was satisfactory" in 13. In 78 knees, one or more of the pathological findings mentioned under A, B, C and D were found. The incidence of 'not satisfactory results at follow-up varied from 22 to 42 % when at least one or two pathological findings were present. The highest incidence of "not satisfactory' results (42 %) occurred in conjunction with an eccentric articulation between the femoral and tibial component (D). The results were not significantly worse than the results in the rest of the material (Chi^2 $p = 0.069$).

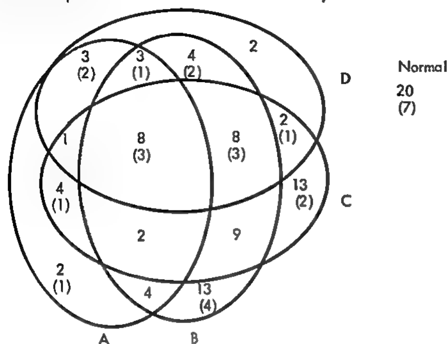
tistical correlation was found between the patients opinion and the evaluation result cording to Weinfeld (Chi^2 p 0.001). The patients opinion at follow-up was not rrelated to disease activity as judged by the presence of pain in other joints. A corre-tion between the patients' opinion at the preliminary examination approximately 12 onths after the operation and their opinion at follow-up, on average 15 months later, owed that 14 knees were considered improved, whereas 26 had deteriorated. The pa-ients were significantly less enthusiastic at follow-up than at the preliminary examina-tion

ARA functional classification

All patients were classified preoperatively and at follow-up according to the American Rheumatoid Arthritis functional system This system was modified by dividing Class III into subgroups a and b Patients in subgroup IIIa were assessed as being able to remain in that class with continued treatment, but patients in subgroup IIIb (patients at risk) were in danger of deteriorating to group IV unless radically treated.

Table 46



ARA	Preoperatively	Follow-up
II	3	19
IIIa	59	47
IIIb (risk)	31	28
IV	16	15

Improved 34
Unchanged 54
Worse 21

The improvement was significant (Wilcoxon s SRT p – 0 015). It must be remembered that in 65 knees, pain at weight-bearing was present in at least one other major joint in the lower extremities Correlation was also found between the result at follow-up accor-dick to Weinfeld and the ARA classification.

The functional improvement reflected in an improved ARA classification did not lead to significant change in socio-economic conditions

Fig. 33. Major pathological roentgen findings at follow-up.
(Numbers in parentheses show the "not satisfactory results at follow-up)

A: FT-angle <168° or >180°

B: Inclination of the tibial component >10°

C: Loosening of the tibial components

1) Change of inclination exceeding 10° or

2) Breakage or buckling of indicator wire

D: Eccentric articulation between femoral and tibial components

(Inadequate data: 11).

Percentage of "not satisfactory" results at follow-up (%)	37	29	23	42	23	27	40	22	39	37	35	29

Patients' opinion at follow-up

11 patients stated that they would not have agreed to an operation had they known the final result. Two had a "satisfactory" and nine a 'not satisfactory' result according to Weinfeld's point system. For a more precise idea of the patients' impression of the result, the following four possibilities were suggested

able 45.

Almost normal	39
Improved	51
Unchanged	10
Deteriorated	9

Statistical correlation was found between the patients opinion and the evaluation result according to Weinfeld (Chi^2 p 0.001). The patients opinion at follow-up was not correlated to disease activity as judged by the presence of pain in other joints. A correlation between the patients opinion at the preliminary examination approximately 12 months after the operation and their opinion at follow-up, on average 15 months later, showed that 14 knees were considered improved, whereas 26 had deteriorated The pa- t ents were significantly less enthusiastic at follow-up than at the preliminary examination

ARA funct onal classification

All patients were classified preoperatively and at follow-up according to the American Rheumato d Arthritis functional system This system was modified by dividing Class III into subgroups a and b Patients in subgroup IIIa were assessed as being able to remain in that class with continued treatment, but patients in subgroup IIIb (patients at risk) were in danger of deteriorating to group IV unless rad cally treated.

Table 46

ARA	Preoperatively	Follow-up
II	3	19
IIIa	59	47
IIIb (risk)	31	28
IV	16	15

Improved	34
Unchanged	54
Worse	21

The improvement was significant (Wilcoxon s SRT p = 0.015). It must be remembered that in 65 knees, pain at weight-bearing was present in at least one other major joint in the lower extremities. Correlation was also found between the result at follow-up accordick to We nfeld and the ARA classification.

The functional improvement reflected in an improved ARA classification d d not lead to any significant change in socio-economic conditions

DISCUSSION

Following a Marmor arthroplasty in the Lund material there were 76 knees (70 %) with "satisfactory" results and 33 (30 %) with "not satisfactory" results after an observation period of 2.2 years (1.0-3.6).

The unconstrained total principle has only been in clinical use for about five years and therefore only a few series observed for more than two years have been published, none as far as is known restricted only to RA. Marmor (1976a), who developed the modular prosthesis reported 88 % excellent to good results in a series of 124 operated OA + RA knees with observation time > 2 years. Insall et al. (1976) reported 64 % excellent to good results in a mixed RA + OA series of 42 knees with observation time > 2 years using the duocondylar prosthesis. Cavendish et al. (1978), Engelbrecht et al. (1976) and Shaw et al. (1978) reported 85-90 % excellent to good results using the Liverpool Mark II, St. Georg Schlitten and Manchester prostheses in OA and RA. The observation time exceeded two years in these series.

Except for Insall et al. (1976), who reported results worse than those presented in this series, other series seem to have only one-third to one-half as many 'not satisfactory" results than was found in the Lund material. Differences in evaluation and populations could explain the discrepancy but indications, details in prosthetic design and operative technique could account for real difference in results.

Loosening

Marmor (1976) reported loosening of the tibial components in 9 % of operated knees. Most of them were overweight OA patients where 6 mm components were used. In other reported series, the incidence of loosening was reported to be from 0-5 % (Engelbrecht et al. 1976, Insall et al. 1976, Laskin et al. 1976, Shaw et al. 1978).

In Lund, loosening of tibial components with considerable clinical symptoms was found in seven knees (6.5 %), but these were only a small fraction of the knees where roentgen at follow-up indicated loosening of tibial components. In the medial compartment 39 % and in the lateral compartment 25 % of the prostheses were loose. Loosening was significantly more common in the medial compartment than in the lateral probably because the 6 mm component was most often used medially.

Change of position

Baldursson et al. (1979) by roentgenstereophotogrammetry in one Marmor arthroplasty

without infection or clinical signs of prosthetic loosening, showed a migration of the tibial component with tilting. Similar examinations have shown migration of acetabular cups in hip arthroplasties. This migration of polyethylene components was considered a general phenomenon and they considered the radiolucent zone found around implants to indicate small movements or a continuous migration of the prosthesis. Insall et al. (1976) found a radiolucent zone under the tibial components in about 50 % of knees and explain this finding as a result of insufficient anchorage and caused by the elastic properties of polyethylene.

In the Lund material, the angle between the longitudinal axes of the tibia and a plane through the indicator wire changed ≧ 5° in 132 of 187 tibial components examined. A radiolucent line ≧ 1 mm was seen under 95 of 162 components. A significant correlation was found between loosening and changed position and between the presence of a zone ≧ 1 mm and change of position.

In conclusion the present concept of unconstrained prostheses for practical use has considerable disadvantages. Wear of the tibial component results in a guiding through and the prosthesis therefore is no longer strictly unconstrained. The elastic properties of polyethylene favour loosening, which occurs early if thin components are used. Migration of polyethylene components seems to take place even if obvious loosening is not present. These observations are an indication for concern in the long-term use of this prosthetic principle. The wear could be reduced by using radiation improved polyethylene, as suggested by Grobbelaar et al. (1978) and the unfavourable effects of the elastic properties of polyethylene could perhaps be prevented by using metal interposed between polyethylene and bone cement (Goodfellow and Connor 1978) and thin tibial components should be avoided.

Contraindications

Contraindications vary in published clinical reports. An extension defect up to 20° was accepted by Engelbrecht et al. (1976), and Laskin et al. (1976). Cavendish et al. (1978) accepted up to 30°. Marmor (1976a) did not consider an extension defect of 60° in an ankylosed knee to be a contraindication. In the Lund series there was an extension defect exceeding 30° in four knees; full correction was obtained in only two of these. If an extension defect was not fully corrected, significantly worse results were found at follow-up and the need for support on walking was increased.

Engelbrecht et al. (1976) accepted varus or valgus up to 20°, Cavendish et al. (1978) and M[illegible] (1976a) used 30° as a limit. In the Lund series clinical malalignment up to

20° was accepted and the result at follow-up was not significantly influenced by the degree of malalignment found preoperatively.

Engelbrecht et al. (1976) and Shaw et al. (1978) draw attention to ligamentary insufficiency in general. Cavendish et al. (1978) found posterior dislocation and Insall et al. (1976) found rotation deformity or subluxation of special importance as contra ndications In the Lund material preoperative lateral subluxation of the tibia was a relative contra-indication.

The anterior drawer sign has from a perusal of the literature not been mentioned as a contraindication. Cavendish et al. (1978) claimed that absence of the anterior cruciate ligament was not important In this series, the preoperative drawer sign was not associated with a significantly worse result (Chi^2 p = 0.079), probably because an anterior drawer sign is an unreliable indication of the absence of the anterior cruciate ligament in a destroyed rheumatoid knee. At follow-up, a significantly worse result was found when the anterior drawer sign existed (Chi^2 p = 0.041). Correlation was also found between the anterior drawer sign and lateral instability at follow-up (Chi^2 $p < 0$ 0001), which implied that two-dimensional instability was often present. In eight operations where the insertion of the anterior cruciate ligament was damaged, five had a not satisfactory" result at follow-up. This finding also indicated the importance of internal stability.

Lateral stability was important. Only 2 of 39 knees with instability between 10 and 20° had an excellent result. Five knees with instability more than 20° had a poor result. Results were significantly worse when lateral instability was found at follow-up Loosening and altered position of the tibial components, from the preliminary examination to follow-up gave rise to lateral instability. Stability acquired at operation was not always maintained. In eight knees where unsatisfactory congruency between the femoral and the tibial components was obtained at surgery, a total collapse of the tibial condyles occurred in spite of cementation in the desired position These findings suggest the need for a review of the operative technique or the limits for indication

On the basis of reported contraindications in published clinical series and in this material, an unconstrained arthroplasty can only be recommended when an extension defect preoperatively is less than 20° and full extension can be achieved without anterior inclination of the tibial prosthesis Varus and valgus malposition should not exceed 20°, antero-posterior and lateral stability must be achieved at the operation and congruency between femoral and tibial components must be satisfactory. It is often imposs ble to predict whether these demands can be fulfilled at operation and it is therefore mandatory to be able to choose another form of arthroplasty if necessary.

The indications used in this series did not exceed recommendations of published works but on the other hand late synovectomy probably was preferred in many cases where others found arthroplasty suitable.

Surgical technique

Marmor (1976a) considered it a major concept in design that the tibial components should be placed in an exactly reamed excavation within the cortical rim In this series an important modification was introduced (Fig. 30). The tibial condyles were resected with an osteotome and the components were anchored with circumferential cortical support. This modification, partly inspired by the operative technique in McIntosh arthroplasty, was technically simple and the cortical rim acting as a support was considered important for keeping the prosthesis permanently in position On roentgenological finding of loosening of one-third of the tibial components and change of position from the first postoperative examination to follow-up, it was obvious that this technique did not fulfil the expectations of stable anchorage and the modification of the operative technique therefore was hardly motivated

Complications

Deep infection was reported by Marmor (1976a) in 7/126 cases (5.6 %), and also had a high incidence of wound healing problems (34 %), prophylactic antibiotics were not used None of the other series earlier referred to, including the Lund series, reported more than 0-2 % deep infections. Although bone cement is used and the operation time is 1-2 hours, deep infection has not been a quantitative problem.

FP-joint Engelbrecht et al (1976), Insall et al (1976) and Sneppen et al. (1978) considered FP-joint problems the most usual reason for pain at follow-up Sneppen et al. claimed that dislocation of the patella was an important reason. Marmor (1976b) reported that 21 % of 345 operated cases had retropatellar pain and in 6 % impingement was found Patellectomy was considered a possibility by Engelbrecht et al (1976) and Marmor (1976a) but it was regarded contraindicated by Insall et al (1976) because it did not prevent pain and usually caused quadriceps insufficiency.

In the Lund material, an impingement of the patella on the anterior edge of one or both femoral components was noted at operation in 15 knees and patellectomy was performed in 12 which resulted in significantly decreased quadriceps power and in five knees extension defects were present at follow-up. Patellectomy was also found to predispose to complicated wound healing In five knees with painful crepitations postoperatively, patellectomy was performed in one, and the pain diminished spontaneously in four.

It can be concluded that FP-joint problems are considerable in this type of arthroplasty and are not connected to any special model of modular design. Except for prevention of unnecessary prominence of the anterior edge of the femoral component, no acceptable treatment of this complication has been suggested.

SUMMARY

109 knees in 90 patients with RA were operated with the Marmor prosthesis from 1974 through 1977. At follow-up 2.2 years (1.0-3.6) postoperatively, an arbitrarily chosen degree of normalization, 0-6 points according to Weinfeld's evaluation system - "satisfactory" results - was achieved in 76 of 109 knees (70 %). Of 33 knees with ≧ 7 points - "not satisfactory" result - 21 were improved, 2 unchanged and 10 worse. The arthroplasty resulted in a reduction of pain, diminished extension defect and lateral instability and correction of malposition at weight-bearing. Quadriceps power increased and the need for support on walking was reduced. Flexion was not significantly changed. As judged by the patients 90 knees were improved and 19 unchanged or worse. There was a significant improvement in ARA functional classification.

Technical difficulties or operative complications occurred in 40 % of the operated knees. Predisposing factors for "not satisfactory" results were fracture of the tibial spine, cementation problems of the tibial components and when congruency between the femoral and tibial components were not achieved. Impingement of the patella on the femoral components treated by patellectomy resulted in weakening of the quadriceps and increased the risk of complicated wound healing which was the most usual postoperative complication (10 %).

Impingement problems were also found postoperatively, but pain and crepitation diminished spontaneously in 4 of 5 knees. Late infection developed in two knees.

Loosening of components with clinical symptoms of a severity that required reoperations occurred in nine; in two, the femoral component could be recemented, but in seven with loosening of the tibial component, arthrodesis or arthroplasty using another type of prosthesis was performed. A review of the roentgen material showed that approximately one-third of inserted tibial components were loose and a change in position of the component had occurred. These findings are probably precursors of future severe problems and are symptoms of failure of the unconstrained principle.

The use of 6 mm components and the insertion of the tibial components with circumferential underlying cortical bone support, probably an advantage for preventing compression but insufficient for withstanding the shearing forces, contributed to the high frequency of loosening in this material.

The restricted indications for unconstrained arthroplasty are due to the imperfections of the available design and the requirement of sufficient soft tissue stability. On the basis of present experience, unconstrained arthroplasty can be recommended if late synovectomy cannot be expected to result in an acceptable reduction of pain and permit walking. Extension defect and malposition should not exceed 20°. At surgery, antero-posterior stability and lateral stability as well as congruency between the femoral and the tibial components must be achieved. Because of the difficulties in predicting whether these requirements can be fulfilled, other prosthetic alternative should always be available.

It can be concluded that FP-joint problems are considerable in this type of arthroplasty and are not connected to any special model of modular design. Except for prevention of unnecessary prominence of the anterior edge of the femoral component, no acceptable treatment of this complication has been suggested.

SUMMARY

109 knees in 90 patients with RA were operated with the Marmor prosthesis from 1974 through 1977. At follow-up 2.2 years (1.0-3.6) postoperatively, an arbitrarily chosen degree of normalization, 0-6 points according to Weinfeld's evaluation system - "satisfactory" results - was achieved in 76 of 109 knees (70 %). Of 33 knees with ≧ 7 points - "not satisfactory" result - 21 were improved, 2 unchanged and 10 worse. The arthroplasty resulted in a reduction of pain, diminished extension defect and lateral instability and correction of malposition at weight-bearing. Quadriceps power increased and the need for support on walking was reduced. Flexion was not significantly changed. As judged by the patients 90 knees were improved and 19 unchanged or worse. There was a significant improvement in ARA functional classification.

Technical difficulties or operative complications occurred in 40 % of the operated knees. Predisposing factors for "not satisfactory" results were fracture of the tibial spine, cementation problems of the tibial components and when congruency between the femoral and tibial components were not achieved. Impingement of the patella on the femoral components treated by patellectomy resulted in weakening of the quadriceps and increased the risk of complicated wound healing which was the most usual postoperative complication (10 %).

Impingement problems were also found postoperatively, but pain and crepitation diminished spontaneously in 4 of 5 knees. Late infection developed in two knees.

Loosening of components with clinical symptoms of a severity that required reoperations occurred in nine; in two, the femoral component could be recemented, but in seven with loosening of the tibial component, arthrodesis or arthroplasty using another type of prosthesis was performed. A review of the roentgen material showed that approximately one-third of inserted tibial components were loose and a change in position of the component had occurred. These findings are probably precursors of future severe problems and are symptoms of failure of the unconstrained principle.

VI. STATISTICAL ANALYSIS OF TOTAL MATERIAL AND SUBSETS

240 knees arthroplasties were performed at the Department of Orthopaedic Surgery, University Hospital of Lund from 1967 through 1976. This material was composed of three subsets:

1) 67 knees operated with unconstrained hemi-arthroplasty (McIntosh).

2) 64 knees operated with constrained arthroplasty (Guépar).

3) 109 knees operated with unconstrained total arthroplasty (Marmor).

POPULATION DIFFERENCES AND EQUALITIES IN SUBSETS

In this material, all knees were similarly evaluated using identical parameters. The three subsets were analysed for equalities and differences in population according to a variety of pre- and postoperative criteria, considered to have a potential influence on the results (Table 47). A Chi^2-test was performed for each criteria; if the p-value was less than 0.05, the subsets were judged significantly different. The three subsets were all identical according to 15 criteria. The McIntosh and Guépar subset were identical according to one criteria, the McIntosh and Marmor subset to nine criteria, and the Guépar and Marmor subset to five criteria. Observation time was significantly different for all three subsets.

Population differences in subsets of major importance for comparison

The observation period in the Marmor material was significantly shorter, i.e. 2.2 years as opposed to 2.7 years in the Guépar material and 3.4 years in the McIntosh material.

In the Guépar material, increased incidence was found of bony attrition at operation, possibly caused by a longer period of disease involvement in the involved knee. Increased deformity such as extension defects and varus- and valgus malpositions, and decreased quadriceps power was noted in the Guépar subset. Increased need for support on walking and the patient's lower functional classification according to the ARA system was primarily due to the condition of the involved knee, because duration of general disease, ESR, serology, pain at weight-bearing in other joints and previous arthroplasties in other joints were identical in the three subsets. As a consequence of the radicality in the Guépar arthroplasty, significantly worse results were not shown in the light of these population differences, but it does not exclude that worse results could have been expected if these patients had been totally unselected and operated with McIntosh or Marmor arthroplasty.

VII. GENERAL DISCUSSION

RESULTS

By compar ng the frequencies of pathological findings preoperatively and at follow-up in the three arthroplasty materials, the extent to which the methods were effective can be assessed Th s is illustrated in the Venn diagrams on pages 25, 55 and 70 as well as by the other criteria included in Weinfeld s evaluation system.

Table 48
Calculated % from Venn diagrams pages 25, 55 and 70.

%	McIntosh (67)		Guépar (64)		Marmor (109)	
	Preop	Follow-up	Preop	Follow-up	Preop	Follow-up

II	75	51	84	10	79	53
III	25	6	44	3	30	5
I+II	72	37	73	2	73	17
I+III	24	6	36	0	28	0
II+III	19	3	30	2	22	2
I+II+III	18	3	27	0	21	0
Outside d agram	0	27	0	64	0	44

I Pain

Pain was a major indication in 88 % – 97 % of the knees. The difference in the subsets was not significant At follow-up, pain was found in 60 % in the McIntosh material, in 25 % in the Guépar material and in 17 % in the Marmor material.

II Instability – varus/valgus malposition

Preoperative lateral instability and/or malposition exceeding 10° at weight-bearing was present n 75 % (McIntosh) to 84 % (Guépar) of knees, the Guépar material had a higher frequency of extreme malposition and varus was more usual than valgus. At follow-up, correction of malposition and/or lateral instability was significantly better when using the Guépar, only 10 % were not corrected as compared to 51 % and 53 % for the McIntosh and Marmor arthroplasties, respectively Lateral instability and/or malposition after Guépar arthroplasty was caused of eccentric position of the prosthesis in the marrow

DISCUSSION

In clinical work, it is usually necessary to accept differences in compared populations. Normally, the population characteristics are so complex that for practical use it seems more realistic to ignore the differences than to define them. This causes much uncertainty in assessment and might lead to serious errors. Tew and Waugh (1978), on the basis of five arthroplasty materials evaluated according to the criteria recommended by the British Orthopaedic Association Research Subcommittee showed that only average age at operation was equal in these series whereas the difference in all the other registered preoperative criteria was highly significant ($p < 0.001$) which implies that these materials were statistically different populations and therefore direct comparison between them is of doubtful relevance.

The three subsets in this work were characterized by a high degree of equality in population, the difference were well defined and comparisons therefore are permitted with an acceptable level of certainty.

VII. GENERAL DISCUSSION

RESULTS

By comparing the frequencies of pathological findings preoperatively and at follow-up in the three arthroplasty materials, the extent to which the methods were effective can be assessed This is illustrated in the Venn diagrams on pages 25, 55 and 70 as well as by the other criteria included in Weinfeld s evaluation system.

Table 48
Calculated % from Venn diagrams pages 25, 55 and 70

%	McIntosh (67)		Guépar (64)		Marmor (109)

II+III	19	3	30	2	22	2
I+II+III	18	3	27	0	21	0
Outside diagram	0	27	0	64	0	44

I Pain

Pain was a major indicat on in 88 % – 97 % of the knees The difference in the subsets was not significant. At follow-up, pain was found in 60 % in the McIntosh material, in 25 % in the Guépar mater al and in 17 % in the Marmor material.

II Instability – varus/valgus malposition

Preoperat ve lateral instability and/or malposition exceeding 10^{o} at weight-bearing was present in 75 % (McIntosh) to 84 % (Guépar) of knees, the Guépar material had a higher frequency of extreme malposition and varus was more usual than valgus. At follow-up, correct on of malposition and/or lateral instability was significantly better when using the Guépar, only 10 % were not corrected as compared to 51 % and 53 % for the McIntosh and Marmor arthroplasties, respectively. Lateral instability and/or malposition after Guépar arthroplasty was caused of eccentric position of the prosthesis in the marrow

cavities or loosening secondary to deep infection. After hemiarthroplasty the following reasons for instability and/or malposition were found 19 knees had severe attrition of one or both femoral condyles which developed after insertion of the prosthesis (Fig. 6a and b). A significantly worse result was found when attrition had developed in the femoral condyles. In 30 knees malposition of one or both prostheses was found, in 20 of them this increased or developed entirely during the observation period. In unconstrained total arthroplasty (Marmor), resurfacing was done on both the femur and the tibia and postoperative attrition therefore prevented. Loosening of one or both tibial components in 44 knees and altered position of one or both tibial components was found in 40 of 86 knees. The common use of a 6 mm tibial component was considered an important reason for the high rate of loosening and alteration of position. Ligamentary insufficiency was also important with regard to instability following Marmor arthroplasty. Where congruency was obviously not achieved at surgery, subluxation and collapse of medial compartment occurred.

III. Extension defect

The preoperative frequency of extension defect in the Guépar material (44 %) was significant greater, than in the McIntosh and Marmor materials. In constrained arthroplasty, an extension defect could be eliminated regardless of the amount. A risk with extreme resection of bone was the development of an extension lag, in two knees (3 %), an extension lag exceeding 20° was found at follow-up. Compared with the unconstrained principle, the result was very satisfactory. In unconstrained arthroplasty, an extension defect can be corrected by resection of the anterior edge of the tibial plateau. The tibial component must often of necessity be placed in an anterior inclination if full extension is to be achieved. Even though significantly worse results at follow-up after McIntosh and Marmor arthroplasty were not shown when extension defects were present at surgery, it must be considered a disadvantage that the normal dorsal translocation of the femur in relation to the tibia on flexion was probably diminished as a result of anterior inclination. After McIntosh arthroplasty, an extension defect exceeding 15° was found at follow-up in four knees (6 %), in Marmor arthroplasty in four knees (5 %). Independent of arthroplasty principle, a significant decrease of operative extension defect was achieved.

Flexion. Limited flexion was not of major importance as an indicat on in any of the knees. When extension defects were eliminated at operation, it was not always possible to increase the range of motion by the amount that the extension defect was diminished, probably because of a decreased amplitude in the extensor apparatus Consequently because of a higher incidence of considerable extension defects preoperatively in the

Guépar material a higher frequency of knees with less than 80° flexion was found after constrained arthroplasty

Quadriceps power Preoperative weak quadriceps was significantly more often present in the Guépar material than in the other two subsets, also at follow-up, weak quadriceps was more often present following constrained than unconstrained arthroplasty. This might to some extent be caused by the extension lag after correction of large extension defects in the Guépar material This can also possibly be accounted for by the inbuilt hyperextension in the Guépar prosthesis which permits walking without contraction of the quadriceps. From the preliminary examination to follow-up, there was a decrease in quadriceps power in the Guépar material probably secondary to loosening of the prosthesis. After unconstrained hemi- and total arthroplasty, there was equal frequencies of weak quadriceps. Increased frequency of pain at weight-bearing in the McIntosh material at follow-up led one to expect a higher frequency of weak quadriceps in this material, but it was probably compensated for by the lower average age in this subset

Conclusion of result at follow-up

Following arthroplasty, the minimum expectation was that the knees postoperatively and at least for some years should be almost painfree, stable and free of deformity and this was so after Guépar arthroplasty in 64 % of the knees, after Marmor arthroplasty in 44 % and after McIntosh arthroplasty in 27 % The constrained principle produced according to these criteria a better result than did unconstrained arthroplasty, although 25 % of the knees at follow-up were still considerable painful.

A comparison of hemi- with unconstrained total arthroplasty showed that they were equally able to correct lateral instability, malposition and extension defect. After hemiarthroplasty, there was an unacceptable frequency of pa n at follow-up in 60 % compared to only 17 % after unconstrained total arthroplasty. The McIntosh hemiarthroplasty was not superior to the Marmor arthroplasty in any aspect discussed here and can no longer be regarded as a rational alternative in surgery of the knee in RA.

cavities or loosening secondary to deep infection. After hemiarthroplasty the following reasons for instability and/or malposition were found 19 knees had severe attrition of one or both femoral condyles which developed after insertion of the prosthesis (Fig. 6a and b). A significantly worse result was found when attrition had developed in the femoral condyles. In 30 knees malposition of one or both prostheses was found, in 20 of them this increased or developed entirely during the observation period. In unconstrained total arthroplasty (Marmor), resurfacing was done on both the femur and the tibia and postoperative attrition therefore prevented. Loosening of one or both tibial components in 44 knees and altered position of one or both tibial components was found in 40 of 86 knees. The common use of a 6 mm tibial component was considered an important reason for the high rate of loosening and alteration of position. Ligamentory insufficiency was also important with regard to instability following Marmor arthroplasty. Where congruency was obviously not achieved at surgery, subluxation and collapse of medial compartment occurred

III. Extension defect

The preoperative frequency of extension defect in the Guépar material (44 %) was significant greater, than in the McIntosh and Marmor materials In constrained arthroplasty, an extension defect could be eliminated regardless of the amount. A risk with extreme resection of bone was the development of an extension lag, in two knees (3 %), an extension lag exceeding 20° was found at follow-up. Compared with the unconstrained principle, the result was very satisfactory. In unconstrained arthroplasty, an extension defect can be corrected by resection of the anterior edge of the tibial plateau The tibial component must often of necessity be placed in an anterior inclination if full extension is to be achieved. Even though significantly worse results at follow-up after McIntosh and Marmor arthroplasty were not shown when extension defects were present at surgery, it must be considered a disadvantage that the normal dorsal translocation of the femur in relation to the tibia on flexion was probably diminished as a result of anterior inclination After McIntosh arthroplasty, an extension defect exceeding 15° was found at follow-up in four knees (6 %), in Marmor arthroplasty in four knees (5 %) Independent of arthroplasty pr nciple, a significant decrease of operative extens on defect was achieved

Flexion. Lim ted flex on was not of major importance as an ind cation n any of the knees. When extension defects were eliminated at operation, it was not always possible to increase the range of motion by the amount that the extens on defect was d minished, probably because of a decreased amplitude in the extensor apparatus Consequently because of a higher incidence of considerable extens on defects preoperatively in the

Extension defect	2	4	4
Incongruency	2	–	7
Cementation problems	–	–	7
Miscellaneous	–	–	9
TOTAL	25 (37 %)	32 (50 %)	58 (53 %)

Operative fractures The most usual type of fracture in McIntosh and Marmor arthroplasty was detachment of the eminentia resulting in loosening of the insertion of the anterior cruciate ligament which resulted in sagittal instability.
In Guépar arthroplasty, 5 of 6 fractures were perforations of the femoral and the tibial diaphyses which occurred during reaming or at insertion of the prosthesis although continuity of the bone was present, the results were uniformly "not satisfactory".

FP-joint problems. In McIntosh arthroplasty, the FP-joint was not influenced by the operation. In only one knee with lateral subluxation of the patella preoperatively was the patella found dislocated postoperatively
In Guépar arthroplasty, a hemiarthroplasty is automatically performed in the FP-joint, but the trochlea of the prosthesis is not anatomical in design. During the operation, 17 knees had dislocation of the patella. Although precautions were taken dislocation was found in two knees postoperatively. The reason for the high frequency of dislocated patella in Guépar arthroplasty was probably multifactorial, but the forced outward rotation of the tibia by traction on the patella ligament during lateral dislocation of the patella during cementing was considered important. In operative patellar dislocations the risk of complicated wound healing increases. No increased risk of late infection was shown
In 15 knees, where Marmor arthroplasty was done, the anterior edge of one or both prostheses was prominent in facies patellaris and at flexion impinged on the patella. Patellectomy was indicated in 12 knees because of impingement.

Incongruency. In unconstrained arthroplasty incongruency at surgery indicated a poor prognosis because the fundamental need for soft tissue stability was not achieved.

Sum demerit points	14.5	8.8	17.9	6.7	15.3	5.7

Preoperatively, there was a significantly higher score in the Guépar material and the average improvement in points was higher than in the other subsets, as a percentage of the preoperative score, the improvement was equal in the Guépar and the Marmor materials. Preoperatively, the McIntosh material had the lowest point score and at follow-up the highest point score, which implies the worst result. At follow-up, the lowest average point score was found in the Marmor material.

COMPLICATIONS

Technical difficulties and operative complications reflect the difficulties with a chosen technique and the pathological changes present in the knee in reconstructing a stable, mobile articulation. In the Guépar material, increased deformity was found preoperatively, but despite that, there was a lower frequency of complications than in the Marmor material.

Collapse of condyles	3	-	3
Fractures	2	1	2
Miscellaneous	-		2
TOTAL	8 (12 %)	21 (33 %)	16 (14.6 %)

Late infection. After McIntosh arthroplasty, no incidence of late infection was noted, although no prophylactic antibiotics were used. In Guépar arthroplasty, late infection developed in 15 knees, in only four was there delayed wound healing. Increased frequency of deep infection was found after transfer of the tibial tuberosity and when no prophylactic antibiotics were used. The consequence of deep infection was considerable, two patients died of septicaemia, one above-knee amputation was carried out on vital indication and five were reoperated with change of prosthesis or arthrodesis. After Marmor arthroplasty, deep infection developed in two knees, one patient died of septicaemia caused by haematogenous spread from an infected varicose ulcer.

Dislocation of the patella. After McIntosh arthroplasty, lateral dislocation of the patella was found in one knee. This was probably secondary to subluxation of the tibia. After Guépar arthroplasty, the patella dislocated laterally in five knees. Reoperation with capsular plication or transfer of the tibial tuberosity was performed in three. In the Marmor material, no additional FP-joint problems developed after two months had elapsed since surgery

Loosening of prosthesis - dislocation. After McIntosh arthroplasty, dislocation of the prosthesis was found in two knees with severe clinical symptoms. After Marmor arthroplasty, total collapse with a compression fracture and loosening of the prosthesis in the medial compartment developed in six knees where congruency between the tibial and the femoral components was not achieved at surgery. Because of the short observation period in the Marmor material and a known high frequency of loosening of components, an in[illegible]cation can be predicted.

Cementation problems. In Marmor arthroplasty in seven knees, stable fixation of one or both tibial components was not achieved at the first cementing attempt. Lack of jigs and instruments for fixing the prosthesis in the desired position during cementing was considered the main reason for these failures.

Table 51.

Postoperative complications (complications noted less than two months after operation).

	McIntosh (67)	Guépar (64)	Marmor (109)

Fractures	-	1	1
Others	2	1	9
Total local complications	8 (12 %)	21 (33 %)	35 (32 %)

Complicated wound healing

After Guépar arthroplasty, complicated wound healing was found in 13 knees (20 %). The frequency was thus twice as high as in Marmor arthroplasty, although the extremity was immobilized in plaster for two weeks for optimum wound healing. Detachment of the tuberosity and dislocation of the patella at surgery and postoperatively predisposed to delayed wound healing. Prophylactic antibiotics had no influence on the frequency of complicated wound healing. In four knees with wound healing problems, a late infection developed afterwards (resulting in one death, one above-knee amputation, and one change of prosthesis). The time spent in hospital was increased on average 44 % when complicated wound healing was present. In the Marmor material an increased frequency of complicated wound healing after patellectomy and previous knee operations was found.

FP-joint problems. In two knees, the patella dislocated laterally after Guépar arthroplasty, although a capsular plication was carried out at surgery. After Marmor arthroplasty in five knees, crepitations and femoro-patellar pain on flexion were caused by

impingement of the patella on the anterior edge of the femoral component, in four, the pain later diminished without treatment.

Table 52.
Late postoperative complications.

	McIntosh (67)	Guépar (64)	Marmor (109)
Late infection	-	15	2
Dislocation of the patella	1	5	-
Dislocation of prosthesis	2	-	7
Collapse of condyles	3	-	3
Fractures	2	1	2
Miscellaneous	-		2
TOTAL	8 (12 %)	21 (33 %)	16 (14.6 %)

Late infection. After McIntosh arthroplasty, no incidence of late infection was noted, although no prophylactic antibiotics were used. In Guépar arthroplasty, late infection developed in 15 knees, in only four was there delayed wound healing. Increased frequency of deep infection was found after transfer of the tibial tuberosity and when no prophylactic antibiotics were used. The consequence of deep infection was considerable, two patients died of septicaemia, one above-knee amputation was carried out on vital indication and five were reoperated with change of prosthesis or arthrodesis. After Marmor arthroplasty, deep infection developed in two knees, one patient died of septicaemia caused by haematogenous spread from an infected varicose ulcer.

Dislocation of the patella. After McIntosh arthroplasty, lateral dislocation of the patella was found in one knee. This was probably secondary to subluxation of the tibia. After Guépar arthroplasty, the patella dislocated laterally in five knees. Reoperation with capsular plication or transfer of the tibial tuberosity was performed in three. In the Marmor material, no additional FP-joint problems developed after two months had elapsed since surgery.

Loosening of prosthesis – dislocation. After McIntosh arthroplasty, dislocation of the prosthesis was found in two knees with severe clinical symptoms. After Marmor arthroplasty, total collapse with a compression fracture and loosening of the prosthesis in the medial compartment developed in six knees where congruency between the tibial and the femoral components was not achieved at surgery. Because of the short observation period in the Marmor material and a known high frequency of loosening of components, an increase of this complication can be predicted.

Collapse of condyles. After McIntosh arthroplasty, a progressing collapse developed in the lateral femoral condyle in two knees and in one with a primary demiarthroplasty, an increasing destruction of the other compartment was noted. After Marmor demiarthroplasty there was a collapse in the non-operated compartment in 3 of 9 knees and reoperation with insertion of a prosthesis in this compartment was carried out. In another two considerable pain was experienced at weight-bearing. Unicompartment operation did not seem to be justified in RA even if one compartment at surgery was found well preserved.

VIII. SUMMARY

Functional results

On Weinfeld's evaluation there was a significantly higher preoperative score and at follow-up the highest improvement in points in constrained arthroplasty (Guépar), but the percentage of improvement was equal in both the constrained and unconstrained (Marmor) total arthroplasty. The lowest point score at follow-up, which implies the best result according to Weinfeld's evaluation system, was found in the Marmor material. The lowest preoperative and the highest follow-up score was found in the McIntosh material which implies that the result in hemiarthroplasty is inferior to total arthroplasty. Following arthroplasty the minimum expectation was that the knees postoperatively and at least for some years thereafter should be relatively painless, stabile and free of deformity. These demands were fulfilled after constrained arthroplasty in 64 % of the knees, after unconstrained total arthroplasty in 44 %, and after hemiarthroplasty in 27 % of the knees. The constrained principle which secures correct alignment of femur and tibia and lateral stability and elimination of extension defect gave better results than the unconstrained arthroplasty although 25 % of the knees at follow-up still had considerable pain.

Technical difficulties and operative complications

The lowest incidence of technical difficulties or operative complications was seen in hemiarthroplasty (McIntosh) in 25 knees (37 %). The dominant problems were detachment of the anterior cruciate ligament, presence of subchondral cysts and attrition of condyles, which made the prosthetic principle insufficient for reconstruction.

The most severe pathological changes were found in the Guépar material. In 32 (50 %) of the constrained arthroplasties, technical difficulties or complications were noted. "Not satisfactory" results were found after perforation of the diaphysis, although continuity of the bone was present allowing full weight-bearing. After correction of extreme extension defects remaining extension lag was found in two knees. Considerable FP-joint problems were noted, operative dislocation of the patella was common and regarded as generally caused by forced outward rotation of the tibia and the shape of the patella facet on the prosthesis.

The highest incidence of technical difficulties and operative complications were found in unconstrained total arthroplasty (Marmor) in 58 knees (53 %). Damage to the insertion of the anterior cruciate ligament, difficulties in cementation of the tibial components, incongruency between femoral and tibial components and passive extension defects were

Collapse of condyles. After McIntosh arthroplasty, a progressing collapse developed in the lateral femoral condyle in two knees and in one with a primary demiarthroplasty, an increasing destruction of the other compartment was noted. After Marmor demiarthroplasty there was a collapse in the non-operated compartment in 3 of 9 knees and reoperation with insertion of a prosthesis in this compartment was carried out. In another two considerable pain was experienced at weight-bearing. Unicompartment operation did not seem to be justified in RA even if one compartment at surgery was found well preserved.

caused by a too optimistic use of the method in knees where the pathological changes were too advanced and partly caused by the lack of jigs for resection and for retaining the tibial components during cementation In the FP–joint, the prosthesis had a harmful effect. Prominence of the anterior edge of the femoral component caused patella impingement, patellectomy was therefore indicated in 12 knees.

Postoperative complications

The lowest incidence of complications was found after hemiarthroplasty (McIntosh). The wound in only four knees failed to heal within four weeks.

After constrained arthroplasty (Guépar), there were no general complications of a serious nature. In two knees, the patella dislocated postoperatively, although operative capsular plication was done. The biggest problem was complicated wound healing in 20 % of the knees. Patellar dislocation and transfer of the tibial tuberosity operatively predisposed to delayed wound healing. Complicated wound healing resulted in an increase of hospital stay and late infection developed in four of the knees.

After unconstrained total arthroplasty (Marmor), there was the same incidence of complications as after Guépar arthroplasty (32 %) Impingement of the patella on the femoral prosthesis caused by its design and position, was noted in five knees In two knees, prosthetic components were loose in the postoperative period. In 10 % of the knees, the wound failed to heal within four weeks, patellectomy predisposed to complicated wound healing.

Late complications

Following hemiarthroplasty (McIntosh), the important complications were dislocation of the prosthesis and collapse of the non-resurfaced condyles.

After constrained arthroplasty (Guépar), the dominating problems were late infections in 15 knees (23 %) with serious consequences such as death, amputation and change of prosthesis. Dislocation of the patella occurred during the observation period in five knees

After unconstrained total arthroplasty (Marmor), loosening of the prosthetic components was found in seven knees and in three knees, primary demiarthroplasties were reoperated with a prosthesis in the other compartment because of collapse of this non-operated compartment.

DEFINITION

The author defines a popliteal cyst as a communicating gastrocnemio semimembranosus bursa which is constantly or temporarily distended by synovial fluid, and not as a cyst originating from the tendon sheath of the popliteus muscle

INTRODUCTION

EARLY CLINICAL OBSERVATIONS CONCERNING POPLITEAL CYSTS

The first mention of a cystic swelling in the popliteal region was made by *Dupuytren*, who in *1829* reported on a patient with an enormous hydrops in the knee joint. In 1840 *Adams* described in detail a chronic inflammatory knee disease which he was the first to designate "chronic rheumatoid arthritis". He believed that the first link in the morbid chain was the disease of the synovial membrane, contradicting Cruveilhier, among others, who considered that the disease started in the cartilage ("usure des cartilages"). He also stated that the affection was very chronic and impossible to cure although it was sometimes benefited by rest. In a comprehensive review concerning abnormal conditions of the knee joint (1839—1847), Adams reported that in the majority of such *cases he had palpated* a cystic tumour in the medial part of the popliteal region, in fact so often that he considered this to be a reliable symptom of the rheumatic joint affection. *On inspection it took the shape of a very well* defined ovoid projection adjacent to the inner hamstring muscles, which was felt to be very tense in the extended position. He stated "If we feel this bursa and then cause the patient's limb to be flexed, we can follow the fluid with our fingers into the articulation". Through his own dissections he established that this cyst mainly consisted of an enlargement and "dropsical condition" of the bursa which naturally exists at the decussation of the semimembranosus tendon with the tendon of the internal head of the gastrocnemius. Adams found that in some cases this enlarged bursa communicated with the joint by "a species *of valvular opening*". In other cases small round apertures into the joint were observed.

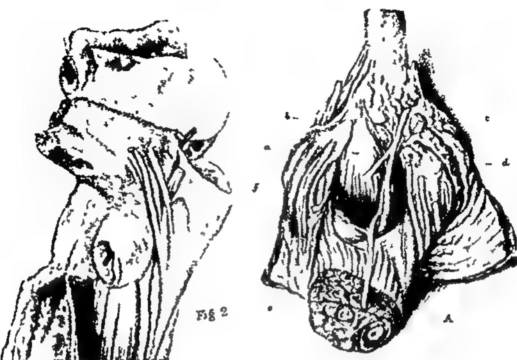

Figure 2 Intermuscular synovial cysts in knee joints amputated because of tuberculous arthritis and dissected by Powers (1885 1887)

purulent inflammation, such as subcutaneous discission, opening and stuffing or packing, or the insertion of setons Numerous fatal complications were reported as a result of such treatment (Gruber 1846, Heineke 1868, Baker 1877, Gribbon 1885) Surgical removal seems to have been performed for the first time by Malgaigne, in the early 1850's—one of his two patients died of septicaemia Only few excisions are reported from the antiseptic era, as disastrous complications were common Since the introduction of asepsis several reports of uncomplicated surgical interventions in popliteal cysts have been made (Bond 1890, Hutton 1895, Sheild 1898, Hawkes 1899)

In a large number of knee dissection studies *Gruber* examined the posterior syno vial recesses, protrusions and communicating bursae (*1845, 1846, 1857, 1865, 1869,* 1885) He formulated the concept of synovial herniation which was subsequently adopted by many authors Gruber published several papers concerning "hygromas of enormous size" which he had observed by chance at routine post-mortem examinations (Figure 1) Regarding the clinical implications he concluded that in below-knee amputations the risk of an ascending knee joint arthritis via a communicating hernia had to be taken into account and suggested aspiration of the knee effusion through the bursa to minimise this hazard This was done by Pitha (1846) *in a young man, but a fulminant* arthritis rapidly developed and the patient died of septicaemia Gruber also dissected *several amputation specimens and reported* a popliteal fistula arising from a bursal perforation in a case of gonococcal arthritis and a large fistular system extending down to the tendon of Achilles in another case

In contrast to Gruber, *Foucher* (1856) found in post-mortem studies that all cysts arose from a bursa and none from synovial herniation ("   et ne comme un diverticu lum, un hernie de la synoviale articulaire") *Foucher also referred to clinical reports on* his own patients and those of contemporary physicians and noted that popliteal cysts could be emptied into the joint cavity by manual compression if the joint was in the flexed position, whereas this was never pos sible with the knee extended This phenomenon has since been confirmed by other authors and has been referred to as the "sign of Foucher" (Heineke 1868, Goldscheider 1898)

Several doctoral theses have been devoted to the clinical aspects, pathogenesis and therapy of popliteal cysts, especially in the early French literature (Nelaton 1851, Longy 1852, Burguet 1854, Ollivier 1855, Baudouin 1855, Garnier 1890, Hemet 1900, Ciolina 1904)

In his two classic papers of 1877 and 1885, *Baker* reviewed two patients of his own and eight patients treated by contemporary physicians who had cystic tumours in the popliteal region He drew attention to the formation of synovial cysts in the leg in connection with disease of the knee joint and to the fact that most often the knee disease had be gun some time before the appearance of the (secondary) cyst Commonly the joints were affected by what Baker called osteoarthritis He was not particularly specific about the pathogenesis of the cysts He considered that their formation was due to the fact that synovial fluid makes its way out of the knee, and for most cases he held the hernial concept of Gruber, Billroth and others, whereas for some he conceded that rupture of a com *municating bursa or of a synovial hernia* had allowed the cyst to form Five of Baker's patients eventually underwent amputation *through the thigh*

Power (1885, 1887), on examination of these amputation specimens, found severe destruction due to articular tuberculosis He exhibited some specimens at the Pathological Society of London and outlined the extension of the cysts and their communication with the joint cavity (Figure 2) In our day Maudsley and Arden (1961) have reviewed the clinical findings in Baker's patients and come to the conclusion that most of them suffered from tuberculosis of the joint and two from rheumatoid arthritis A histopathological re examination of Baker's knee specimens which have been preserved at St Bartholomew's Hospital Museum was undertaken by Gask and Wilson, who found that they displayed signs of typical synovial tuberculosis

During the "days of laudable pus" con servative treatment with counter irritation, compression and vesication with collodion and pressure and the application of a plaster-of-Paris bandage was common practice (Kir misson 1892) More invasive methods of treatment did occur, however, such as punc ture and tapping, the injection of Morton's fluid, caustics or iodine and still more agg ressive procedures with the aim of producing

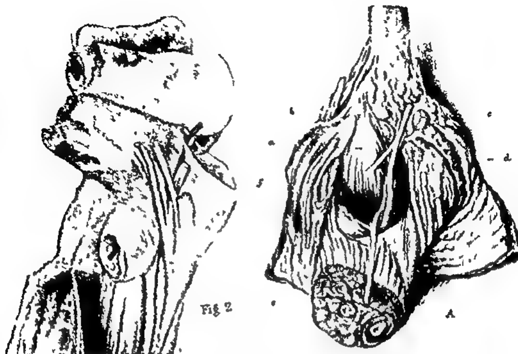

Figure 2 Intermuscular synovial cysts" in knee joints amputated because of tuberculous arthritis and dissected by Powers (1885 1887)

purulent inflammation, such as subcutaneous discission, opening and stuffing or packing, or the insertion of setons Numerous fatal complications were reported as a result of such treatment (Gruber 1846, Heineke 1868, Baker 1877, Gribbon 1885) Surgical removal seems to have been performed for the first time by Malgaigne, in the early 1850's—one of his two patients died of septicaemia Only few excisions are reported from the antiseptic era, as disastrous complications were common Since the introduction of asepsis several reports of uncomplicated surgical interventions in popliteal cysts have been made (Bond 1890, Hutton 1895, Sheild 1898, Hawkes 1899)

In a large number of knee dissection studies *Gruber* examined the posterior synovial recesses, protrusions and communicating bursae (1845, 1846, 1857, 1865, 1869, 1885) He formulated the concept of synovial herniation which was subsequently adopted by many authors. Gruber published several papers concerning "hygromas of enormous size" which he had observed by chance at routine post-mortem examinations (Figure 1) Regarding the clinical implications he concluded that in below-knee amputations the risk of an ascending knee joint arthritis via a communicating hernia had to be taken into account and suggested aspiration of the knee effusion through the bursa to minimise this hazard This was done by Pitha (1846) in a young man, but a fulminant arthritis rapidly developed and the patient died of septicaemia Gruber also dissected several amputation specimens and reported a popliteal fistula arising from a bursal perforation in a case of gonococcal arthritis and a large fistular system extending down to the tendon of Achilles in another case

In contrast to Gruber, *Foucher* (1856) found in post-mortem studies that all cysts arose from a bursa and none from synovial herniation (" et ne comme un diverticulum, un hernie de la synoviale articulaire") Foucher also referred to clinical reports on his own patients and those of contemporary physicians and noted that popliteal cysts could be emptied into the joint cavity by manual compression if the joint was in the flexed position, whereas this was never possible with the knee extended This phenomenon has since been confirmed by other authors and has been referred to as the "sign of Foucher" (Heineke 1868, Goldscheider 1898)

Several doctoral theses have been devoted to the clinical aspects, pathogenesis and therapy of popliteal cysts, especially in the early French literature (Nelaton 1851, Longy 1852, Burguet 1854, Ollivier 1855, Baudouin 1855, Garnier 1890, Hemet 1900, Ciolina 1904)

In his two classic papers of 1877 and 1885, *Baker* reviewed two patients of his own and eight patients treated by contemporary physicians who had cystic tumours in the popliteal region He drew attention to the formation of synovial cysts in the leg in connection with disease of the knee joint and to the fact that most often the knee disease had begun some time before the appearance of the (secondary) cyst Commonly the joints were affected by what Baker called osteoarthritis He was not particularly specific about the pathogenesis of the cysts. He considered that their formation was due to the fact that synovial fluid makes its way out of the knee, and for most cases he held the hernial concept of Gruber, Billroth and others, whereas for some he conceded that rupture of a communicating bursa or of a synovial hernia had allowed the cyst to form Five of Baker's patients eventually underwent amputation through the thigh

Power (1885, 1887), on examination of these amputation specimens, found severe destruction due to articular tuberculosis He exhibited some specimens at the Pathological Society of London and outlined the extension of the cysts and their communication with the joint cavity (Figure 2) In our day *Maudsley and Arden (1961)* have reviewed the clinical findings in Baker's patients and come to the conclusion that most of them suffered from tuberculosis of the joint and two from rheumatoid arthritis A histopathological re examination of Baker's knee specimens which have been preserved at St Bartholomew's Hospital Museum was undertaken by Gask and Wilson, who found that they displayed signs of typical synovial tuberculosis

During the "days of laudable pus" conservative treatment with counter-irritation, compression and vesication with collodion and pressure and the application of a plaster-of-Paris bandage was common practice (Kirmisson 1892) More invasive methods of treatment did occur, however, such as puncture and tapping, the injection of Morton's fluid, caustics or iodine and still more aggressive procedures with the aim of producing

Figure 3 Illustrations from Gruber s classical monograph Die Knieschleimbeutel (bursae mucosae synoviales) from 1857 showing synovial outpouchings through the tendon of the gastrocnemius muscle

the knee there was only a narrow slit Several authors, including Brösicke (1899), Bardeleben Haeckel (1901) Fick (1904), Merkel (1907) Sonntag (1916—17) and Lewin (1952) have since agreed with this view

Most anatomists have reported an approximately 50% frequency of communication between the G S bursa and the joint, but few have given consistent details, e g age, sex and state of the joint of the subjects from whom the specimens were obtained

In the present century few basic investigations concerning the anatomy of popliteal bursae have been performed

Wilson et al (1938), emphasizing the bursal origin of the popliteal cysts, undertook a dissection study of the postero medial knee region in 30 adult cadavers and distinguished six primary bursae which it seemed could coalesce with one another or be subdivided Like many earlier anatomists they differentiated between the bursa lying beneath the medial gastrocnemius tendon and that between the gastrocnemius and semimembranosus tendons, which in 26 cases had fused to form one composite bursa These investigators were also the first to point out that the communication is situated beneath the origin of the inner head of the gastrocnemius and that the bursa has no neck or stalk leading into the joint, as this innermost portion consists only of a synovial lining of the capsule Although this study has been widely quoted by contemporary surgeons (Burleson et al 1956, Childress 1970, Justis 1971), the idea of a narrow neck still predominates Wilson and co workers also prepared casts of the bursa by injecting paraffin mixed with radio paque lipoidol, which enabled them to locate the bursa at post mortem radiography and to study the casts for the impressions which the bursa had sustained from the capsular opening and from the surrounding tendons

Lindgren (1977) examined the radiogra

THE ANATOMY OF THE POSTERO-MEDIAL KNEE BURSAE

Albinus (1734) was the first anatomist to make mention of bursae at the postero-medial aspect of the knee joint (see also frontispiece) The one situated between the semimembranosus tendon and the capsule he denominated "bursa parva", and that beneath the medial head of the gastrocnemius muscle he called the "bursa magna" The latter bursa he found to be firmly adherent to the tendinous part of the gastrocnemius and semitendinosus muscles and the capsule overlying the medial femoral condyle

Monro (1788) (Alexander Monro secundus) published a beautifully illustrated monograph of all the bursae mucosae of the human body One postero-medial bursa he called the "bursa vesicularis postica ad latus genus" This opus was considerably enlarged by *Rosenmuller* for the German edition of 1799

The pathologist *Gruber* performed several series of meticulous dissection studies on at least 700 knees (1845, 1846, 1856, 1857, 1865, 1869, 1885) He gave a correct description of the gastrocnemio semimembranosus (g-s) bursa although he did not name it, and stated that it communicated with the joint in about 50% and more commonly in robust persons and especially in men He filled the communicating bursa by insufflating air into the joint through a patellar drill hole In a large number of dissections in children he never found a communication, even though the bursa was constantly observed not only in newborn infants but also in foetuses In monkeys, on the other hand, he never saw this bursa He also described a separate, hitherto unknown bursa beneath the uppermost part of the gastrocnemius located above the femoral condyle, which he named the "bursa supracondyloidea (interna)" In his classic monograph "Die Knieschleimbeutel (bursae mucosae genuales)" he gave a detailed description of this bursa, which did not communicate with the joint

Gruber considered that most of the communicating cavities were formed by synovial outpouching (Ausstulpung), whereas only one-third were communicating bursae He also described and illustrated greatly varying and bizarre synovial protrusions through gaps in the gastrocnemius tendon and also the constriction of the neck which these protuberances sustained from such gaps Two of these illustrations are reproduced in Figure 3 Regarding the aforementioned giant cysts, he claimed that some did not communicate with the joint cavity and thus constituted bursal hygromas Gruber's concept of synovial protrusion has since been widely adopted in both the clinical and anatomical literature

Heineke (1868) wrote a monograph concerning knee bursae and *Synnestvedt* (1869) presented a doctoral thesis on bursae mucosae, for which he received an award, based on a limited number of his own dissections and a survey of the contemporary literature Synnestvedt carefully differentiates between the "bursa semimembranoso-gastrocnemialis" and "bursa musculi gastronemii interni" and is the last author to mention the bursa supracondyloidea (interna) described by Gruber

Poirier (1886) defended the concept of two separate bursae around the medial belly of the gastrocnemius even though they often coalesce He recognised that only this bursa could transform into a clinically manifest popliteal cyst and therefore designated it "*bourse des kystes poplités*" By injecting warm coloured suet he obtained casts of these bursae At their upper pole he discovered small processes ("proces synoviaux sous condyliens") He also pointed out the intimate connection between the bursal wall and the tendons and questioned whether even the most skilful surgeon could enucleate a popliteal cyst in its entirety

The anatomist *Henle* (1872) gave the most detailed description of the communication to be found in the literature He stated, however, that the opening was very wide when the knee was extended and that on flexion of

Gruber considered that most of the communicating cavities were formed by synovial outpouching (*Ausstulpung*), whereas only one third were communicating bursae He also described and illustrated greatly varying and bizarre synovial protrusions through gaps in the gastrocnemius tendon and also the constriction of the neck which these protuberances sustained from such gaps Two of these illustrations are reproduced in Figure 3 Regarding the aforementioned giant cysts, he claimed that some did not communicate with the joint cavity and thus constituted bursal hygromas Gruber's concept of synovial protrusion has since been widely adopted in both the clinical and anatomical literature

Heineke (1868) wrote a monograph concerning knee bursae and *Synnestvedt* (1869) presented a doctoral thesis on bursae mucosae, for which he received an award, based on a limited number of his own dissections and a survey of the contemporary literature Synnestvedt carefully differentiates between the "bursa semimembranoso gastrocnemialis" and "bursa musculi gastronemii interni" and is the last author to mention the bursa supracondyloidea (interna) described by Gruber

Poirier (1886) defended the concept of two separate bursae around the medial belly of the gastrocnemius even though they often coalesce He recognised that only this bursa could transform into a clinically manifest popliteal cyst and therefore designated it "bourse des kystes poplites" By injecting warm coloured suet he obtained casts of these bursae At their upper pole he discovered small processes ("proces synoviaux sous condyliens") He also pointed out the intimate connection between the bursal wall and the tendons and questioned whether even the most skilful surgeon could enucleate a popliteal cyst in its entirety

The anatomist *Henle* (1872) gave the most detailed description of the communication to be found in the literature He stated, however, that the opening was very wide when the knee was extended and that on flexion of

association with popliteal cysts Not least, it is interesting to note that a *diligent survey* of these papers and the illustrations given in *them does not reveal any true* hernial protrusion On the contrary, all cases can be identified as originating from the communicating gastrocnemio semimembranosus bursa with the site of communication high up beneath the gastrocnemius tendon (Lindgren 1979), which is in agreement with the findings in a recent prospective arthrographic investigation of 41 popliteal cysts (Lindgren & Rauschning 1979) Regardless of whether popliteal cysts are considered to be synovial protrusions or distended bursae, most surgeons state that the cyst has an attachment to the postero medial aspect of the knee joint capsule Occasional cases of communication with the joint in the central portion of the popliteal space and even communications situated beneath the posterior oblique ligament have been reported, however (Haggart 1938)

Descriptions of the surgical anatomy are unspecific about the location and shape of the communication with the joint, as well as about the topographic relationship to adjacent anatomical structures, and opinions are greatly divided concerning the optimum sur[illegible]

[illegible] 1949, Anson & Maddock 1952, Lewin 1952, Apley 1968, Aegerter & Kirkpatrick 1975)

Reports have varied considerably concerning the *frequency of communication* as observed at operation In adults a frequency of more than 50% and up to 100% has been reported by surgeons who have published large [illegible]

[illegible] seen, 50% when it was absent, Wilson et al 1938 98%, Meyerding & van Demark 1943 100%, Burleson et al 1956 65%, Childress 1970 73%, Vahvanen 1973 86%) Infantile popliteal cysts are commonly claimed to lack a communication with the joint (Morscher 1957, Malloch 1970, Borellini et al 1971) However, Touloukian (1971) and Gristina & Wilson (1964) each found 11 communicating cysts at 20 and 23 operations, respectively

In the opinion of some surgeons *closure of the communication* is unnecessary or not possible owing to the size of the opening (Moser 1950, Burleson et al 1956, Crasselt 1966, Justis 1971, Smillie 1974, Hort 1975) Most authors, however, apart from a radical excision of the cyst, advocate closure of the communication (Bond 1890, Kirmisson 1892, Hawkes 1899, Hemet 1900, Wilson et al 1938, Edmunds & Hebble 1939, Meyerding & van Demark 1943, Haggart 1943, Kuhn & Hemphill 1944, Sachs & Rubinstein 1946, Orr 1951, Saegesser 1956, Kirpilä & Ripatti 1958, Beatty 1959, Harvey & Corcos 1960 Colombo 1965, Bryan et al 1967, Borellini et al 1971, Justis 1971, Solomon & Berman 1972, Goldstein & Dickerson 1974) Plastic aponeurotic procedures using free tendon grafts to close the opening in the capsule have been performed by Haggart (1938) and Childress (1954, 1970)

In some larger reviews the results of *histopathological examination* of excised popliteal cysts have been reported (Hammer 1920, Haggart 1938, Wilson et al 1938, Buck et al 1943 Kuhn & Hemphill 1944, Burleson et al 1956, Kirpilä & Ripatti 1958, Harvey & Corcos 1960 Hoffman 1963, Myles 1971, *Reinhardt 1972), but no consistent* histological features have been described upon which a clinically *relevant classification* could be based or conclusions drawn regarding their pathogenesis

In the literature numerous accounts bear witness to the propensity of popliteal cysts to recur following surgical excision (Lewin [illegible]

[illegible] particularly after their removal in children (Malloch 1970 Dinham 1975) In a recent clinical and arthrographic follow up study Rauschning & Lindgren (1979) found 40 recurrences and 15 postoperative complications following 41 routine operations on such cysts

phic morphology of the communicating gastrocnemio-semimembranosus bursa, using plaster-of-Paris to prepare the casts Corresponding radiographs and casts obtained during knee flexion and extension allowed an investigation of the functional radiographic anatomy of the bursa *Moser* (1950) undertook dissection studies and concluded that the communication between the joint cavity and bursa can result from violent hyperextension

Recently Lindgren & Willen (1977) performed post-mortem arthrography, dissections, light microscopic and scanning electron microscopic investigations of postero-medial knee capsule specimens from subjects of different age groups They demonstrated that the opening between the joint and the bursa constantly had the shape of a cranially oriented transverse slit in the joint capsule and that the gastrocnemio-semimembranosus bursa more frequently communicated with the joint cavity with increasing age In older age groups they found degenerative changes in the capsular wall and also in the broad *layer of fibroelastic tissue which in most* young persons separates the joint from the bursa No essential morphological differences were noted between the synovial lining of the bursa and that of the joint, but the degenerative changes in the bursa were more pronounced when it was in communication with the joint

RECENT INVESTIGATIONS ON POPLITEAL CYSTS (20th CENTURY)

Though the current opinion today tends towards the view that popliteal cysts develop from distension of a communicating knee bursa (Wilson et al 1938, Morscher 1957, Hoffman 1963, Gristina & Wilson 1964, Bryan et al 1967, Perri et al 1968, Goldstein & Dickerson 1974, Smillie 1974), the concept of a hernial origin still widely prevails (Cravener 1932, Haggart 1938 and 1943, Edmunds & Hebble 1939, Meyerding & van Demark 1943, Kuhn & Hemphill 1944, Sachs & Rubinstein 1946, Wiles 1949, Lewin 1952, *Kirpilä & Ripatti 1958, Beatty 1959, Colom*bo 1965, Wieser et al 1967, Solomon & Berman 1972, Pinder 1973, Aegerter & Kirkpatrick 1975)

Other clinicians consider both modes of cyst formation possible (Burleson et al 1956, Ackerman 1959, Hoffman 1963, Justis 1971) The following is a list of some clinical synonyms of popliteal cysts, which also provide an indication of the assumption concerning their mode of development

Baker's cyst, Popliteal hernia, Posterior herniation of the knee joint, Kyste synovial herniaire, Popliteal ganglion, Arthrozele, Popliteal synovial herniation, Gastrocnemio-semimembranosus bursa, Medial gastrocnemius bursitis, Semimembranosus bursa, Semimembranosus bursitis, Bursitis semimembranacea, Semimembranaceuszysten, Popliteal bursitis, Intrapopliteal bursitis, Zystische Bursitis, Synoviazyste, Popliteazyste, Poplitealzyste, Popliteogene Unterschenkelzyste, Bursal cysts, Hygroma, Zystisches bursales Hygrom, Synoviales Kystom, Cystic bursal hygromas, Intermuscular synovial cysts

Lately comprehensive *arthrographic studies* of the posterior recesses of the knee and of the communicating popliteal cavities have been performed with the use of positive contrast medium, and strong evidence in *favour of the development of popliteal cysts* from the communicating postero-medial bursa has been produced, (Ficat 1957, Kessler & Silberman 1960, Doppman 1965, Fischedick 1969, Lapayowker et al 1970, Fischedick 1971, Pallardy et al 1971, Reinhardt 1972, Solomon & Berman 1972, Wolfe & Coloff 1972, Pulich 1975, Etienne et al 1976, Lindgren 1977, Matthias 1977, Lindgren 1978) Many investigators point out the discrepancy between the radiographically high incidence of communicating bursae—which should not be called Baker's cysts as they are artificially distended (Rauschning & Lindgren 1979) —and the relative infrequency of clinically palpable popliteal cysts Arthrography has also proven of value for the diagnosis of intrinsic disorders of the knee, which are frequently found in

association with popliteal cysts Not least, it is interesting to note that a diligent survey of these papers and the illustrations given in them does not reveal any true hernial protrusion On the contrary, all cases can be identi- [illegible]

the gastrocnemius tendon (Lindgren 1979), which is in agreement with the findings in a recent prospective arthrographic investigation of 41 popliteal cysts (Lindgren & Rauschning 1979) Regardless of whether popliteal cysts are considered to be synovial protrusions or distended bursae, most surgeons state that the cyst has an attachment to the postero medial aspect of the knee joint capsule Occasional cases of communication with the joint in the central portion of the popliteal space and even communications situated beneath the posterior oblique ligament have been reported, however (Haggart 1938)

Descriptions of the surgical anatomy are unspecific about the location and shape of the communication with the joint, as well as about the topographic relationship to adjacent anatomical structures and opinions are greatly divided concerning the optimum surgical approach for exposure of the opening (Holmes 1870, Billroth 1876, Fullerton 1916, Davis 1918, Piersol 1919, Clark 1949, Wiles 1949, Anson & Maddock 1952, Lewin 1952, Apley 1968, Aegerter & Kirkpatrick 1975)

Reports have varied considerably concerning the *frequency of communication* as observed at operation In adults a frequency of more than 50% and up to 100% has been reported by surgeons who have published large materials (Hoffman 1963 58%, Gristina & Wilson 1964 66%, Bryan 1967 74% when a pathological condition of the joint was present 30% when it was absent, Wilson et al 1938 98%, Meyerding & van Demark 1943 100%, Burleson et al 1956 65%, Childress 1970 73%, Vahvanen 1973 86%) Infantile popliteal cysts are commonly claimed to lack a communication with the joint (Morscher 1957 Malloch 1970, Borellini et al 1971) However, Touloukian (1971) and Gristina & Wilson (1964) each found 11 communicating cysts at 20 and 23 operations, respectively

In the opinion of some surgeons *closure of the communication* is unnecessary or not possible owing to the size of the opening (Moser 1950, Burleson et al 1956, Crasselt 1966, Justis 1971, Smillie 1974, Hort 1975) Most authors, however, apart from a radical excision of the cyst, advocate closure of the communication (Bond 1890, Kirmisson 1892, Hawkes 1899, Hemet 1900, Wilson et al 1938, Edmunds & Hebble 1939, Meyerding & van Demark 1943, Haggart 1943, Kuhn & Hemphill 1944, Sachs & Rubinstein 1946, Orr 1951, Saegesser 1956, Kirpila & Ripatti 1958, Beatty 1959, Harvey & Corcos 1960, Colombo 1965, Bryan et al 1967, Borellini et al 1971, Justis 1971, Solomon & Berman 1972, Goldstein & Dickerson 1974) Plastic aponeurotic procedures using free tendon grafts to close the opening in the capsule have been performed by Haggart (1938) and Childress (1954, 1970)

In some larger reviews the results of *histopathological examination* of excised popliteal cysts have been reported (Hammer 1920, Haggart 1938, Wilson et al 1938, Buck et al 1943, Kuhn & Hemphill 1944, Burleson et al 1956, Kirpilä & Ripatti 1958, Harvey & Corcos 1960, Hoffman 1963, Myles 1971, Reinhardt 1972), but no consistent histological features have been described upon which a clinically relevant classification could be based or conclusions drawn regarding their pathogenesis

AIMS OF THE PRESENT INVESTIGATION

Concerning the surgical anatomy of popliteal cysts the reader both of papers dealing with this subject and of recognised textbooks of anatomy and orthopaedic surgery meets with information that is inconsistent in several respects The aim of the present investigation was therefore to study

1 the origin of popliteal cysts, in order to establish whether they are capsular herniations or fluid distended bursae,
2 the optimum surgical approach to the cyst, particularly its communication with the joint,
3 the topographic anatomy of the deep portion of the cyst, commonly referred to as its neck, pedicle or stalk,
4 the possibility and necessity of isolating the whole cyst,
5 the possibility and necessity of radical removal of all cyst tissue,
6 the detailed anatomy of the communication with respect to its location, shape and width,
7 *the frequency of communication of popliteal cysts as observed during operation,*
8 the presence of any weak portions in the postero medial knee joint capsule,
9 the implications of the joint movement, of tendon pull and of possible capsular tearing forces for the surgical technique,
10 the anatomical prerequisites for achieving a firm and durable closure of the communication

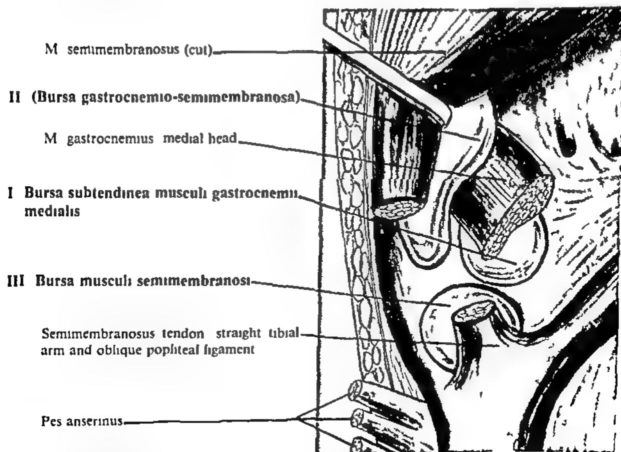

Figure 4 The location of the three knee bursae under study and their current denomination according to the International Anatomical Nomenclature Committee (1966)

ANATOMICAL DISSECTION STUDY

Conventional knife dissections were conducted on human cadavers to clarify the detailed anatomy of the g s bursa and the location of its communication with the joint During these dissections observations were also made concerning capsular tearing forces that might be transmitted to the capsular opening The surgical approach was studied with particular reference to the access to the communication and to the avoidance of damage to cutaneous nerves

MATERIAL

The material was obtained from autopsies at the Department of Pathology, University of Uppsala, in the years 1977 and 1978 The knees of 200 cadavers were examined by palpation, and in no case was a cystic swelling palpable in the popliteal space Among these 200 cases, 54 were chosen for whom a study of the medical records and physical examination revealed no history or signs of rheumatoid arthritis affecting the knee, effusion into the knee joint, or previous knee operations Cardiovascular disorders were the most common cause of death The material thus consisted of 108 non diseased joints Eight subjects were 40—50 years of age at the time of death, and 46 were 51 years of age or older Thirty-five knees were from men and 19 from women

Figure 5 Oblique medial view of a right knee in an autopsy case in the prone position Thigh to the left lower leg to the right After resection of the bursa a plastic band was inserted from the site of the commonly used incision centred over the swelling to demonstrate the conventional path of surgical approach to the communication The decussation of the tendons obstructs the access to the opening in the capsule beneath the gastrocnemius (gc) (interrupted line)
sm = semimembranosus st = semitendinosus g = gracilis sa = sartorius pa = pes anserinus

Upper *The dashed line indicates the incision suggested by the author (extended knee) The semitendinosus serves as a landmark*

Lower *Upon knee flexion the tendons are easily retracted dorsally providing good access to the opening of the capsule (large arrow)*

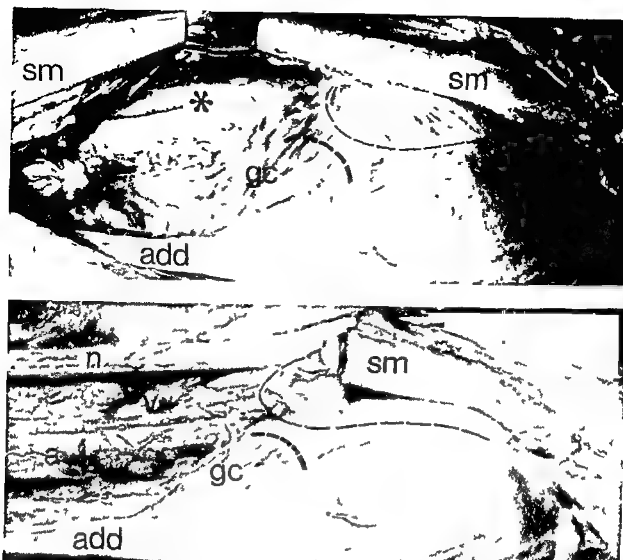

Figure 7 Medial view of a right knee in an autopsy case in the prone position The pes anserinus tendons have been removed The g s bursa bulges beneath the semimembranosus (sm) There is no anatomical obstacle between the bursa and the neurovascular structures (*) The adductor magnus (add) and gastrocnemius (gc) are intimately interwoven Resection of the semimembranosus (lower figure) gives a free view of the popliteal artery (a) vein (v) and nerve (n) The thick dashed line indicates the site of the communication between the joint and the bursa beneath the gastrocnemius tendon

SELECTION OF SPECIMENS AND COURSE OF DISSECTION

All 108 knees were filled with 60—80 ml of saline tinted with methylene blue With the body in the prone position the popliteal fascia was exposed and incised longitudinally along the lateral border of the semitendinosus tendon Upon repeated gentle flexion communicating cysts filled in 58 knees (13 right, 9 left and 18 bilateral), on several occasions with an audible and palpable bruit These were submitted to detailed dissection In all 108 knees the entire posteromedial capsule was transilluminated with fibreoptic light in search for any weak areas

The subcutaneous nerves at the posteromedial aspect of the knee were dissected, the course of the major saphenous nerve in particular The bursae artificially distended with fluid were dissected to clarify the extent of the bursa, its gross anatomy and its topographic relationship to the structures of this region The site of the communication was determined in relation to the origin of the

gastrocnemius tendon The size and shape of the opening was recorded and the deformation of the opening caused by passive movement of the knee as well as by pull on inserting tendons simulating active flexion, was examined. Finally the thickness of the gastrocnemius tendon overlying the capsular aperture was measured at three levels

CUTANEOUS NERVES

The *saphenous nerve* after passing through the subsartorial canal was invariably found to emerge between the sartorius muscle and the gracilis tendon It entered the subcutaneous space by perforating the crural fascia above or at the level of the joint As a rule the nerve joined the great saphenous vein within a few centimetres (Figures 5 and 6) Accessory branches were present in two cases and in one further specimen an extra fascial anatomosis with the cutaneous nerve ending of the anterior division of the obturator nerve was observed The average distance between the saphenous nerve and the medial border of the gastrocnemius tendon at the level of the femoral condyle was 4 cm (range 3—6 cm) The centre of the popliteal region was supplied by terminal branches of the *posterior femoral cutaneous nerve* The number and distribution of nerve endings varied considerably but the saphenous nerve and its branches were oriented in the longitudinal axis of the leg Occasionally fibres from the posterior femoral cutaneous nerve crossed the cyst beneath the popliteal fascia without sending branches to its wall

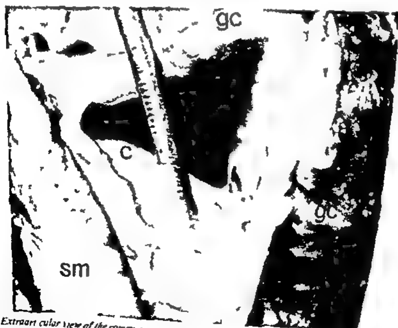

Figure 8 Extraarticular view of the communication in the [illegible] knee from the medio-distal direction The gastrocne[illegible] been resected and the remainder [illegible] lower capsular portion [illegible] dyle (c) is visible throug[illegible]

THE COMMUNICATING BURSA

Of the six primary bursae at the postero-medial aspect of the knee (Wilson et al 1938), only the g s bursa was found to communicate with the knee joint After division of the unyielding popliteal fascia this bursa was invariably found in the sulcus formed by the muscle bellies of the semimembranosus and medial head of the gastrocnemius, the so called sulcus popliteus medialis It was oblong or ovoid, 1—2 cm wide and 3—6 cm long (Figure 7) Its posterior wall was usually slightly lobulated and surrounded by loose areolar tissue No communication with the semitendinosus tendon sheath was seen The lower pole was usually firmly attached to the medial border of the gastrocnemius by a fibrous cord Once this was divided, the bursa could easily be dissected free Towards the decussation of the gastrocnemius and semimembranosus tendons the bursal wall became increasingly adherent As, during knee extension, these tendons were forcefully pressed against each other, flexion of the knee and retraction of the muscles was required to obtain access to the anterior compartments of the bursa (Figures 5 and 6) One constant process of the bursa was situated between the joint capsule and the straight tibial arm of the semimembranosus tendon and occasionally protruded medially (Figure 7) Another compartment of the compound g s bursa consisted of the constant bursa beneath the tendon of the gastrocnemius muscle In 54 cases this bursa had coalesced with the above mentioned bursa between the gastrocnemius and semimembranosus tendons (Figure 8) In four specimens only the small subgastrocnemius bursa filled with fluid from within the joint, while the bursa between the tendons of the gastrocnemius and semimembranosus was empty

Membranes were frequently found within the g s bursa They formed incomplete septa, usually oriented in the sagittal plane Some of the larger g s bursae extended in the cranial direction beneath the semimembranosus tendon, and this portion in particular frequently displayed diverticulae Small branches of the medial superior genicular artery entered the bursa at its upper pole The inner surface of the bursa was often covered with soft synovial ridges Sometimes diverticulae or meshwork of tiny synovial bands were seen especially in the anterior portion Fibrin or mucin clots, as well as cartilage debris and a few rice bodies were contained in some of the bursae

THE COMMUNICATION

In all specimens transillumination disclosed a thin area in the postero medial capsule immediately distal to the 2 5—3 cm broad gastrocnemius tendon insertion (Figures 8 and 9) No such thinning was seen around the oblique popliteal ligament When the bursa communicated with the joint cavity the opening presented as a transverse slit at the uppermost rim of the capsule, separating the capsule from the gastrocnemius tendon opposing the upper lateral circumference of the femoral condyle Its width was 4—24 mm (mean 1 8 mm) The margin was sharply defined and occasionally slightly frayed The slit was situated 2 0—5 5 cm (mean 3 4 cm) distal to the origin of the gastrocnemius tendon From the inside of the joint it re [illegible]

lateral circu[illegible] condyle, thus facing the centre of the popliteal fossa (Figure 7, interrupted line) and was separated from the popliteal nerve and vessels by the broad gastrocnemius muscle belly (Figure 8)

The entire capsular opening was covered by the tendon of the gastrocnemius muscle Opposite the medial edge of the slit it was

Figure 9 Preparation of the postero-medial capsule removed in a frozen state from the left knee of an autopsy speci men

Upper right	*Detail of the communication Behind the broad gap the gastrocnemius tendon (gc) is seen*
Lower right	*The opening viewed from above after horizontal section of the gastrocnemius tendon*

3—7 mm thick (mean 4 8 mm), opposite the mid point of the slit 3—7 mm (mean 4 6 mm) and at the the lateral edge 3—6 mm (mean 3 9 mm) (Figure 9) In three cases a tiny synovial ridge was detected on the arti cular surface of the gastrocnemius tendon, whereas no counterpart for the sharp upper rim of the capsule was seen in the remainder of specimens

When the tibia was rotated at various degrees of knee flexion, the slit was deformed diagonally Pulling on the semimembranosus tendon, particularly with the knee flexed, markedly widened the opening cranio-caudally On several occasions the slit widened owing to further tearing at its edges Simulated hyperextension did not widen the gap, as the capsule was pulled cranially by the semimembranosus tendon, which then acted as a tension band protecting the capsu lar opening

SERIAL CRYOSECTIONING OF UNDECALCIFIED SPECIMENS

A substantial drawback of conventional knife dissection is the increasing difficulty in orientation encountered in the preparative procedure Thus, when the fascia is split the popliteal space pressure decreases, and the collapse of the cyst after escape of its fluid content, together with the distortion resulting from retraction and division of tendons and muscles, make determination of the topography and the dimensions of the cyst difficult The rather complex pluricompartmental extensions of the bursa, and its relationship to the tendons which it covers, are difficult to visualize Moreover, the displacement and compression of popliteal structures caused by a distended cyst are relieved once the fluid-filled cavity is emptied

Ullberg and co-workers (1954, 1977) developed a procedure of cryosectioning of whole animals for autoradiographic and toxicological studies As serial sectioning of the fluid-filled frozen joint would permit a detailed study of the synovial extension of the articular cavity and the bursa, the technique of cryosectioning of large animal specimens was modified A description and discussion of the technique is also given elsewhere (Rauschning 1979)

Figure 11 Serial cryosection ng with a heavy duty cryomicrotome built into a cryostat (LKB 2250 PMW) A human knee joint specimen with a communicat ng popl teal bursa is sectioned in the sagittal plane at —20°C The block is mounted on the hori-ontally moving sledge and the knife is fed downwards to cut sections 5—200 µm thick The debris can be removed by a vacuum cleaner during automatic trimming

MATERIAL AND METHODS

The material consisted of 14 fresh human knee joints Two knees were obtained from above knee amputations for arteriosclerotic gangrene These two amputated knees had no communicating g s bursa one was sec tioned in the horizontal and the other in the sagittal plane (Figure 10) The remaining specimens were obtained at autopsies The subjects were over 50 years of age and all knees were healthy and had not been ope rated upon The presence of a communicat ing bursa in the autopsy cases was ascer- tained as follows With the body in a prone position 60—80 ml of methylene blue- stained water was instilled into the joint and the popliteal fascia was exposed by raising a large rectangular skin flap When at gentle

flexion a communicating cyst could be seen through the fascia, carbon dioxide snow was repeatedly applied between the skin flap and the fascia It took approximately six hours for the knee to become frozen Thus 12 cadaver knees with communicating g s bursae were obtained In one case with bilateral communicating bursae one knee was frozen at maximal extension and the other at about 40° of flexion The remaining 10 knees were frozen at various angles of flexion A block was then cut comprising either the whole popliteal space, including the posterior halves of the femoral condyles and the tibial plateau, or—for sagittal plane sectioning—the postero medial quadrant of the joint containing a larger portion of the medial femoral and tibial condyles

Specimens with a maximum height of about 7 cm were mounted on a large stage, in a semiliquid solution of carboxymethyl cellulose (CMC gel) and then frozen in a container filled with hexane cooled with dry ice to a temperature of about —75°C The freezing time was 20—30 minutes

The block was placed in a plastic bag and stored in a freezer (—25°C) Prior to sectioning the block was left in the microtome cryostat for some hours for thermal equilibration (—20°C) Cracking of the surface was observed if the block was not allowed to accommodate

The specimen was mounted on the sledge of a heavy duty microtome (LKB 2250 PMV Cryo Microtome) The whole frozen specimen was sectioned through and the surface of the block was photographed by the author at consecutive levels (Figure 11)

It was not necessary to collect sections on tape, since the anatomical details were well outlined by their natural colours on the surface of the block Also, the methylene blue stained ice contained in the articular cavities showed up with good contrast The brilliance of the picture was improved if the surface of the block was thawed by rubbing it with a cloth soaked in ethylene glycol

As the control panel of the cryomicrotome could be programmed to cut a predetermined number of sections (1—20) of selected thickness, equidistant intervals for documentation were ensured The maximum microtome knife excursion of 50 mm was increased to approximately 65 mm by intermounting an additional bottom plate More than 1,000 sections were cut from every specimen Ten specimens were sectioned in the transverse plane and four in the sagittal plane

For photography a 35 mm SLR camera equipped with a 50 mm macro lens and an automatic flash was used and photographs were taken on 25 ASA colour film with a gauge placed on the block The magnification on the film could be read directly on the scale of the lens As a rule, photographs were taken at 2 mm intervals The films were studied at intermediate magnification in a light microscope or by projection onto a screen

RESULTS

The tendon of the medial head of the gastrocnemius took the shape of a broad plate and originated from the supracondyloid tubercle and along a crest extending towards the insertion of the adductor magnus tendon Here both tendons were intimately interwoven The muscular portion arose from an area of roughened bone on the popliteal aspect of the femoral shaft The ratio of the muscular to the tendinous portions varied greatly The gastrocnemius tendon covered the lateral half of the posterior curvature of the medial femoral condyle, forming a 4—8 mm thick dome The tendon alone constituted the upper part of the fibrous capsule All fibres were oriented longitudinally and no separate layer of capsular fibres was detected (Figures 12—15) Towards the centre of the popliteal space the muscular portion increased The slit shaped opening into the joint was always completely covered by the tendon (Figures 12 and 15) No sesamoid bone or cartilage was found The neurovascular supply to the muscle was seen on the lateral aspect of the muscle belly below the level of the joint

The straight tibial arm of the semimembranosus tendon had a very broad insertion in the tibia (Figure 12) In both sagittal and horizontal sections the oblique popliteal ligament presented as a diffuse thickening of the fibrous capsule (Figures 12 and 14) Neither above nor below this posterior oblique ligament was any weakening of the capsule detected The posterior horn of the medial meniscus was not firmly attached to this particular portion of the capsule, whereas its postero medial and medial segments were closely interwoven with the capsule, the attachment increasing in the medial direction (Figures 12 and 14)

The thick capsular portion above the oblique popliteal ligament consisted of transversally and diagonally oriented fibrous strands Towards the junction with the gastrocnemius its thickness decreased almost abruptly, and this thin area in the frontal plane was always narrower than the overlying tendon The medial and lateral borders of this "capsular window" consisted of longitudinally oriented fibrous columns No fibrous margin corresponding to the sharply defined rim of the capsule was seen on the articular surface of the gastrocnemius tendon and in no specimen could the former line of attachment be identified Some thin synovial bands, but no membranes, partially bridged the orifice (Figure 12)

With the knee in extension the popliteal artery, vein and nerve lay close to the medial aspect of the lateral femoral condyle During flexion the neurovascular structures retracted away from the capsule posteriorly The broad medial belly of the gastrocnemius muscle was interposed between the site of the capsular opening and the blood vessels and nerves

The communicating g s bursa extended between the tendons of the gastrocnemius and the semimembranosus In one case, however, only the subgastrocnemial bursa was filled with blue ice When the bursa was distended it displaced the gastrocnemius tendon laterally and the semimembranosus tendon medially (Figure 12)

In knees frozen in flexion the posterior joint recesses and the anterior extensions of the g s bursa were wide and filled with ice, and the capsular gap was open (Figures 14 and 15)

During knee extension both the posterior recesses and the subgastrocnemial portion of the bursa were completely emptied and were only discernible as thin blue lines The gastrocnemius tendon was firmly stretched over the condyle, thus compressing the capsular slit The tightly overlying semimembranosus tendon seemed to potentiate this effect (Figure 16) The posterior portion of the bursa bulged beneath the popliteal fascia

Strikingly often the bursal cavities were subdivided by membranes and septa which were not oriented in any particular directions As all compartments of the cyst were filled with methylene blue stained ice, however, they must have been incomplete or perforated (Figures 12—15) The wall of the posterior portion of the bursa was well defined In the deep compartments no separate fibrous wall was seen A synovial lining intimately followed the tendons, the aponeuroses of the muscles and the capsule, and no plane of cleavage was detected

flexion a communicating cyst could be seen through the fascia, carbon dioxide snow was repeatedly applied between the skin flap and the fascia It took approximately six hours for the knee to become frozen Thus 12 cadaver knees with communicating g s bursae were obtained In one case with bilateral communicating bursae one knee was frozen at maximal extension and the other at about 40° of flexion The remaining 10 knees were frozen at various angles of flexion A block was then cut comprising either the whole popliteal space, including the posterior halves of the femoral condyles and the tibial plateau, or—for sagittal plane sectioning—the postero medial quadrant of the joint containing a larger portion of the medial femoral and tibial condyles
